ANATOMY,

DESCRIPTIVE AND SURGICAL.

BY

HENRY GRAY, F.R.S.,

FELLOW OF THE ROYAL COLLEGE OF SURGEONS; LECTURER ON ANATOMY AT ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.

A NEW EDITION, THOROUGHLY REVISED

BY

AMERICAN AUTHORITIES,

FROM THE

THIRTEENTH ENGLISH EDITION

EDITED BY T. PICKERING PICK, F.R.C.S.

WITH 772 ILLUSTRATIONS, MANY OF WHICH ARE NEW.

LEA BROTHERS & CO.,
PHILADELPHIA AND NEW YORK.
1897.
Entered according to Act of Congress, in the year 1897, by
LEA BROTHERS & CO.,
in the office of the Librarian of Congress at Washington. All rights reserved.
TO

SIR BENJAMIN COLLINS BRODIE, BART.,
F.R.S., D.C.L.,
SERJEANT-SURGEON TO THE QUEEN,
CORRESPONDING MEMBER OF THE INSTITUTE OF FRANCE,

This Work is Dedicated

IN ADMIRATION OF

HIS GREAT TALENTS

AND IN REMEMBRANCE OF

MANY ACTS OF KINDNESS SHOWN TO THE AUTHOR

FROM AN

EARLY PERIOD OF HIS PROFESSIONAL CAREER.
In his masterpiece Henry Gray left undying evidence of his anatomical knowledge and of his comprehension of the best method of imparting it to other minds. After forty years its merits are only brightened by the numerous works which have endeavored to contest its supremacy. During that time it has had the benefit of the careful scrutiny of many leading anatomists of the English-speaking race. Anatomy is far from stationary, either in its facts or in improvements in the method of their presentation; hence any work which would faithfully reflect the existing position of the science must be revised at comparatively frequent intervals. Fortunately for students and practitioners, Gray's Anatomy enjoys a demand rendering such revision possible.

An evidence of the unremitting attention bestowed on this book is afforded in the issue now presented. Its basis is found in the revision of 1896 by Professor J. Playfair McMurrich and Dr. B. B. Gallaudet. The new chapters on the Brain and the Abdominal Viscera by Dr. Gallaudet and Dr. F. J. Brockway, respectively, have been retained. The section on the Mouth and Teeth has been rewritten by Prof. H. H. Burchard, who has taken account of the latest advances in the highly specialized department which particularly concerns students and practitioners of Dentistry.

The splendid illustrations in Gray have long been known as the most effective and intelligible presentations of anatomical structures ever produced. In the edition of 1896 this series was increased by the addition of one hundred and thirty-five new pictures. The total of seven hundred and seventy-two illustrations stands unchanged in the new issue, but it includes a large number of new engravings, no expense having been spared to effect improvement wherever possible.

The practical application of anatomical facts in medicine and surgery has always been a prominent feature of the work, and this distinctive characteristic has received especial care.

In short, this edition is presented to the medical public with the confident expectation that it will be found worthy in every respect to maintain the exalted position which the work has for so many years enjoyed as the most convenient and intelligible exposition of its subject.
PREFACE TO THE THIRTEENTH ENGLISH EDITION.

When Henry Gray published this work in 1858, he entitled it Anatomy, Descriptive and Surgical, and he introduced under each subdivision such observations on practical points of Surgery as show the necessity of an accurate acquaintance with the anatomy of the part under examination. This was the first time that such an endeavor had been made by an English Anatomist.

The Editor has endeavored to follow in the lines originally laid down by the Author, and has tried to keep before himself the fact that the work is intended for Students of Surgery rather than for the Scientific Anatomist. Not that the Editor would wish to disparage, for an instant, the study of Philosophical or Scientific Anatomy, but that he thought it right, considering the class of students for whom the work is primarily intended, that he should be practical rather than abstract and theoretical. Accordingly, he has not altered in any way the original plan of the work, but has endeavored to render it more practical, and of more use to the student, who will hereafter have to apply his knowledge of Anatomy to his practice of Surgery, by introducing a considerably increased amount of Surgical Anatomy, and by pointing out the bearings of Anatomy on the practice of Surgery.

In addition to this, the whole work has undergone a careful revision, and in some minor details a rearrangement has been made.

The Editor is deeply indebted to his friend Mr. Ross for much kind assistance in the preparation of this edition, and also for the help that he has rendered him in passing these pages through the press.

To Dr. Leonard Remfry he is also much indebted for his kindness in revising the section on the anatomy of the Female Organs of Generation.

Several new illustrations have been added, principally from dissections in the Hunterian Museum of the Royal College of Surgeons. The Editor takes this opportunity of thanking Prosector Pearson for the kind interest he has displayed and assistance he has rendered in the preparation of these drawings, which were taken from dissections made by this master in the art of dissecting.
Surgical Articulations

Articulations of the Joints

Restructures composing the Joints 313
Articular Lamella of Bone 313
Ligaments 313
Synovial Membrane 313
Bursae 314
Synovia 314
Forms of Articulation:
Synarthrosis 314
Amphiarthrosis 315
Diarthrosis 315
Movements of Joints 316

Articulations of the Trunk

Articulations of the Vertebral Column 319

#### THE VEINS

### General Anatomy

| Subdivision into Pulmonary, Systemic, and Portal | 647 |
| Anastomoses of Veins | 648 |
| Superficial Veins | 648 |
| Deep Veins, Veine Comites | 648 |
| Sinuses | 648 |

#### Pulmonary Veins
| Systemic Veins | 649 |

#### Veins of the Head and Neck

| Frontal Vein | 650 |
| Facial Vein | 650 |
| Surgical Anatomy | 650 |
| Temporal Vein | 650 |
| Internal Maxillary Vein | 650 |
| Temporomaxillary Vein | 650 |
| Posterior Auricular Vein | 650 |
| Occipital Vein | 650 |

#### Veins of the Neck

| External Jugular Vein | 650 |
| Surgical Anatomy | 650 |
| Posterior External Jugular Vein | 650 |
| Anterior Jugular Vein | 650 |
| Internal Jugular Vein | 650 |
| Surgical Anatomy | 650 |
| Lingual Vein | 650 |
| Pharyngeal Vein | 650 |
| Thyroid Veins | 650 |
| Vertebral Veins | 650 |

#### Veins of the Diploe
| Cerebral Veins | 650 |
| Superficial Cerebral Veins | 650 |
| Deep Cerebral Veins | 650 |
| Cerebellar Veins | 650 |

#### Sinuses of the Dura Mater

| Superior Longitudinal Sinus | 650 |
| Inferior Longitudinal, Straight Sinuses | 650 |
| Lateral Sinus | 650 |
| Occipital Sinuses | 650 |
| Cavernous Sinuses | 650 |
| Surgical Anatomy | 650 |

#### Circumflex Iliac Artery
| Course and Relations | 651 |
| Surgical Anatomy | 651 |

#### Internal Iliac Artery
| Course and Relations | 652 |
| Surgical Anatomy | 652 |

#### Anterior Tibial Artery
| Course and Relations | 653 |
| Peculiarities | 653 |
| Surface Marking | 653 |
| Surgical Anatomy | 653 |
| Braches | 653 |

#### Posterior Tibial Artery
| Course and Relations | 654 |
| Peculiarities | 654 |
| Surface Marking | 654 |
| Surgical Anatomy | 654 |
| Braches | 654 |

#### Peroneal Artery
| Course and Relations | 655 |
| Peculiarities | 655 |
| Plantar Arteries | 655 |
| Surface Marking | 655 |
| Surgical Anatomy | 655 |

#### THE VEINS OF THE UPPER EXTREMITY AND THORAX

| Superficial Veins | 656 |
| Deep Veins | 656 |
| Axillary Vein | 656 |
| Surgical Anatomy | 656 |
| Subclavian Vein | 656 |
| Innominate Veins | 656 |
| Peculiarities | 656 |
| Internal Jugular Vein | 656 |
| Inferior Vena Cava | 656 |
| Superior Iliac Vein | 656 |
| Azygos Veins | 656 |
| Branchial Veins | 656 |
| Sinus Veins | 656 |

#### THE VEINS OF THE LOWER EXTREMITY—ABDOMEN AND PELVIS

| Internal Saphenous Vein | 657 |
| External Saphenous Vein | 657 |
| Popliteal Vein | 657 |
| Femoral Vein | 657 |
| Deep Epigastric Veins | 657 |
| Deep Circumflex Iliac Veins | 657 |
| Internal Iliac Vein | 657 |
| Internal Pudic Veins | 657 |
| Common Iliac Veins | 657 |
| Peculiarities | 657 |
| Inferior Vena Cava | 657 |
| Peculiarities | 657 |
| Lumbar Veins | 657 |
| Spermatic Veins | 657 |
| Surgical Anatomy | 657 |
| Ovarian Veins | 657 |
| Renal and Suprarenal Veins | 657 |
| Phrenic Veins | 657 |
| Hepatic Veins | 657 |

1211
GENERAL ANATOMY.

The fluids of the body, which are intended for its nutrition, are the lymph, the chyle, and the blood. There are other fluids also which partially subserve the same purpose, as the saliva, the gastric juice, the bile, the intestinal secretion; and others which are purely excrementitious, as the urine. But there is no need to describe the rest in this place, since they are the secretions of special organs, and are described, as far as is judged necessary for the purposes of this work, in subsequent pages. We shall here speak first of the blood, and next of the lymph and chyle.

THE BLOOD.

The blood is a thickish, opaque fluid, of a bright-red or scarlet color when it flows from the arteries, of a dark-red or purple color when it flows from the veins. It is viscid, and has a somewhat clammy feeling; it is salt to the taste, and has a peculiar faint odor. It has an alkaline reaction. Its specific gravity at 60° F. is about 1.055, and its temperature is generally about 100° F., though varying slightly in different parts of the body.

General Composition of the Blood.—When blood is drawn from the body and allowed to stand, it solidifies in the course of a very few minutes into a jelly-like mass, which has the same appearance and volume as the fluid blood, and, like it, looks quite uniform. Soon, however, drops of a transparent yellowish fluid begin to ooze out from the surface of this mass and to collect around it. Coincidently with this the clot begins to contract, so that, in the course of about twenty-four hours, the original mass of coagulated blood has become separated into two parts—a "clot" or "coagulum," considerably smaller and firmer than the first-formed jelly-like mass, and a large quantity of yellowish fluid, the serum, in which the clot floats.

The clot thus formed consists of a solid, colorless material, called fibrin, and a large number of minute cells or corpuscles, called blood-corpuscles, which are entangled and enclosed in the fibrin. The fibrin is formed during the act of solidification. In the fluid blood in the living body there is a substance, named fibrinogen, which when acted upon by a second material, also contained in the blood, and named a fibrin-ferment, forms a solid substance, fibrin. This latter in its process of solidification encloses and entangles the blood-corpuscles, and thus the clot is formed.

Recent observations have shown that the presence of a trace of a calcium salt is a necessary condition for the transformation of fibrinogen into fibrin. The fibrin-ferment does not exist as such in the blood contained in the blood-vessels, but seems to result from the destruction of what are known as the white corpuscles and the blood-plaques to be described later. These structures, more especially the plaques, disintegrate very rapidly when blood is drawn from the body, liberating the ferment, and so producing coagulation, and lesions of the cells lining the interior of the blood-vessels seem also to give rise to ferment-production and the intra-vascular formation of fibrin.
We may now consider the constituents of the blood in another way. If a drop of blood is placed in a thin layer on a glass slide and examined under the microscope, it will be seen to consist of a number of minute bodies or corpuscles floating in a clear fluid; and, on more minute examination, it will be found that these corpuscles are principally of two kinds. The one, greatly preponderating over the other in point of numbers, is termed the colored corpuscle; the other, fewer in number and less conspicuous, is termed the colorless corpuscle. From this we learn that blood is a fluid holding a large number of corpuscles of two varieties in suspension. The fluid is named *liquor sanguinis* or *plasma*, and must not be confused with the serum spoken of above in connection with the coagulation of the blood. It is serum and something more, for it contains one at least of the elements or factors from which fibrin is formed. The relation of these various constituents of blood to each other will be easily understood by a reference to the subjoined plan:

\[
\text{Blood} \begin{cases} 
\text{Corpuscles} & \text{Colored} \\
& \text{Colorless} \\
\text{Liquor Sanguinis} & \text{Fibrin} \\
& \text{Serum}
\end{cases}
\]

The *blood-corpuscles*, *blood-disks*, *blood-globules* are, as before stated, of two kinds: the red or colored, and the white or colorless corpuscles. The relative proportion of the one to the other has been variously estimated and no doubt varies under different circumstances. Thus venesection, by withdrawing a large proportion of the red globules, and by favoring the absorption of lymphatic fluid into the blood, greatly increases the relative proportion of the white corpuscles. Klein states that in healthy human blood there appears to be one white corpuscle for 600–1200 red ones. The proportion of corpuscles, colored and colorless combined, to liquor sanguinis is in one hundred volumes of blood about thirty-six volumes of the former to sixty-four of the latter.

**Colored corpuscles** when examined under the microscope are seen to be circular disks, biconcave in profile, having a slight central depression, with a raised border (Fig. 1, b). When viewed with a moderate magnifying power, this central depression looks darker than the edge. When examined singly by transmitted light, their color appears to be of a faint reddish-yellow when derived from arterial blood, and greenish-yellow in venous blood. It is to their aggregation that blood owes its red hue. Their size varies slightly even in the same drop of blood, but it may be stated that their average diameter is about \(3\,\mu\text{m}\) of an inch, their thickness about \(\frac{1}{1200}\) or nearly one-quarter of their diameter. Besides these, especially in some anaemic and diseased conditions, certain corpuscles are found of a much smaller size, about one-third or half the size of the ordinary one. These, however, are very scarce in normal blood. The number of red corpuscles in the blood is enormous; between 4,000,000 and 5,000,000 are contained in a cubic millimetre. Power states that the red corpuscles of an adult would present an aggregate surface of about 3000 square yards. Human blood-disks present no trace of a nucleus. They consist of two parts: a colorless envelope, or investing membrane, which is composed largely of fatty material; and a colored fluid contents, which is a solution of a substance named *haemoglobin*. *Haemoglobin* is a proteid compound of a very complex constitution, the haemoglobin of the horse having the formula \(\text{C}_{712}\text{H}_{132}\text{N}_{216}\text{S}_{2}\text{FeO}_{28}\). It has a great affinity for oxygen, and when removed from the body crystallizes readily under certain circumstances. It is readily soluble in water, and the addition of this fluid to a drop of blood speedily dissolves out haemoglobin from the corpuscle.
If the web of a frog's foot is spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the wall of the vessel. Doubtless the same is the case in the human body; but when drawn and examined on a slide without reagents, the blood-globules often collect into heaps like rouleaux of coins (Fig. 1, c).

During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves to some extent to the size of the vessel. They are also highly elastic, for they speedily recover their shape when the pressure is removed. They are soon influenced by the medium in which they are placed, and by the specific gravity of the medium. In water they swell up, lose their shape, and become globular; subsequently the haemoglobin becomes dissolved out, and the envelope can be barely distinguished as a faint, circular outline. Solutions of salt or sugar, denser than the serum, give them a stellate or crenated appearance; and the usual shape may be restored by diluting the solution to the proper point. The same crenated outline may be produced as the first effect of the passage of an electric shock; subsequently, if sufficiently strong, the shock ruptures the envelope. A solution of salt or sugar of the same specific gravity as serum merely separates the blood-globules mechanically without changing their shape.

The white corpuscles (Fig. 2) are rather larger than the red in human blood, measuring from about 2/100 to 2/70 of an inch in diameter. They consist of a transparent granular-looking protoplasm containing one, two, or more nuclei, and presenting bright granules, which vary in different corpuscles both in quantity and in their behavior to micro-chemical reagents. When absolutely at rest they are rounded or spheroidal, but under ordinary circumstances their form is very various, and they have the remarkable property of undergoing "amoeboid" changes (Fig. 3). That is to say, they have the power of sending out finger-shaped or filamentous processes of their own substance, by which they move and take up granules from the surrounding substance.

In locomotion the corpuscle pushes out a process of its substance—a pseudopodium, as it is called—and then shifts the rest of the body into it. In the same way, when any granule or particle comes in its way it wraps a pseudopodium round it, and then, withdrawing it, lodges the particle in its own substance. By means of these amoeboid properties they have the power of wandering or emigrating from the blood-vessels by penetrating their coats, and thus finding their way into the perivascular spaces.

The white corpuscle may be taken as the type of a true animal cell. It has no limiting membrane, but consists of a mass of transparent albuminous substance, called protoplasm, containing one or more nuclei. These nuclei may assume varying shapes, being sometimes spherical, sometimes horseshoe-shaped, sometimes moniliform, these various shapes being transition stages between the mononuclear and polynuclear corpuscles.

The white corpuscles are very similar to, if not identical with, the corpuscles of lymph and chyle, and they also bear a strong resemblance to the cells found
in pus. From the fact that cells exactly like the colorless corpuscles are being
constantly furnished to the blood by the lymphatic vessels and the chyle-ducts,
and also from their varying proportions in different parts of the circulation and
in different pathological conditions, the colorless corpuscles have been regarded
—erroneously, however—as an earlier stage of the colored blood-disks, but the
evidence in favor of this must be regarded as quite inconclusive.

There can be no doubt that during embryonic life the red corpuscles are
developed from mesoblastic cells in the vascular area of the blastoderm. They
are at first nucleated and resemble white corpuscles, except in their color, and,
like them, are possessed of amoeboid movements. They are succeeded by smaller,
non-nucleated corpuscles, having all the characters of adult colored corpuscles,
probably formed by a conversion of the former into the latter. So that at birth
the nucleated red corpuscles have disappeared. In after life an important source
of the red corpuscles is the red marrow of bones, in which certain cells found in
the marrow are converted into colored blood-corpuscles by the loss of their nuclei,
and by their protoplasm becoming tinged with yellow. It is probable, also, that
the spleen may be a place for the formation of red corpuscles. This theory, which
was formerly universally believed, and was then discarded for the hypothesis that
the spleen was concerned in the destruction of the red corpuscles, has lately been
revived by Bizzozero. The question must still be regarded as sub judice. The
proportion of white corpuscles appears to vary considerably in different parts of
the circulation, being much larger in the blood of the splenic vein and hepatic vein
than in other parts of the body, while in the splenic artery they are very scanty.

In addition to these corpuscles, a third variety is found in mammalian blood,
and has been specially studied and described by Hayem, Bizzozero, and Osler.
They are pale circular or oval disks, about one-quarter or one-third the size of the
red blood-corpuscles, and apparently contain no nucleus. They have been named
blood-plates or blood-plaques, and are supposed by Bizzozero to originate the fibrin-
ferment, and to be especially concerned in the coagulation of the blood.

The liquor sanguinis or plasma is the fluid part of the blood, and contains in
solution various organic substances, such as fibrinogen, paraglobulin or serum
globulin, and serum albumen, together with certain salts, sugar, fatty matter, and
gases. Paraglobulin is probably contained partly in solution in the plasma, and
partly in the colorless corpuscles, and can be obtained by diluting the liquor sanguinis
with ten times its volume of ice-cold water, and then transmitting through
it a stream of carbon dioxide. Fibrinogen may be obtained in the same way as
paraglobulin, but the liquor sanguinis must be still further diluted and the current
of carbon dioxide must pass for a much longer time. Fibrin may be obtained
by whipping the blood, after it has been withdrawn from the body, with a bundle
of twigs, to which the fibrin, as it coagulates, adheres. Fibrin may also be
obtained by filtering the freshly-drawn blood of an animal whose corpuscles are
large, care being taken to retard coagulation as long as possible. Under these
circumstances the corpuscles are retained on the filter, and the liquor sanguinis,
passing through, coagulates and separates into fibrin, free from corpuscles, and
serum.

Fibrin, thus obtained, is a white or buff-colored substance, presenting a
stringy appearance, and under the microscope exhibiting fibrillation. When
exposed to the air for some time, it becomes hard, dry, brown, and brittle. It is
a proteid compound, insoluble in hot or cold water, alcohol or ether. Under the
influence of dilute hydrochloric acid it swells up, but does not dissolve; but when
thus swollen it is easily dissolved by a solution of peptic. If heated for a
considerable time in a solution of dilute hydrochloric acid, it gradually
dissolves.

Serum is the fluid liquor sanguinis after the fibrin has been separated from it.
It is a straw-colored fluid having a specific gravity of 1.027, with an alkaline
reaction. Upon boiling it becomes solid, on account of the albumen which it
contains. It contains also salts, fatty matters, sugar, and gases.
Gases of the Blood.—When blood is exposed to the vacuum of an air-pump, about half its volume is given off in the form of gases. These are carbon dioxide, oxygen, and nitrogen. The relative quantities in 100 volumes of arterial and venous blood, at 0° C. and 1 m. pressure of mercury are shown in the accompanying table:

| Venous blood   | 6 to 10 vols.    | 35 vols.                  | 1 to 2 vols.           |

Roughly stated, they are as follows: Carbon dioxide about two-thirds of the whole quantity of gas, oxygen rather less than one-third, nitrogen below one-tenth (Huxley). The greater quantity of the oxygen is in loose chemical combination with the haemoglobin of the blood-corpuscles, but some part is simply absorbed, just as it would be by water. The carbon dioxide is in a state of chemical combination with the salts of the serum, especially the sodium, with which it is combined partly as a carbonate and partly as a bicarbonate. The nitrogen is unimportant. It (or at least the greater part of it) is merely absorbed from the atmosphere under the pressure to which the blood is exposed, and can therefore be mechanically removed.

Blood-crystals.—Hemoglobin, as stated above, when separated from the blood-corpuscles, readily undergoes crystallization. These crystals, named haemoglobin crystals, all belong, with the exception of those obtained from the squirrel, to the rhombic system. In human blood they are elongated prisms (Fig. 4, A). In the squirrel they are hexagonal plates. Other crystals may be obtained by mixing dried blood with an equal quantity of common salt, and boiling it with a few drops of glacial acetic acid. A drop of the mixture placed on the slide will show the crystals on cooling. These are named haemin crystals, and consist of small acicular prisms (Fig. 4, B). Occasionally in old blood-clots a third form of crystal is found, the hematoidin crystal (Fig. 4, C).

**LYMPH AND CHYLE.**

Lymph is a transparent, colorless, or slightly yellow fluid, which is conveyed by a system of vessels, named lymphatics, into the blood. These vessels take their rise in nearly all parts of the body from the interstices of the connective tissue, and take up the fluid contained in these spaces and return it into the veins close to the heart, there to be mixed with the mass of the blood. The greater number of these lymphatics empty themselves into one main duct, the thoracic duct, which passes along the front of the spine and opens into one of the large veins at the root of the neck. The remainder empty themselves into a smaller duct, which terminates in the corresponding vein on the opposite side of the neck.

Chyle is an opaque, milky-white fluid, absorbed by the villi of the small intestines from the food, and carried by a set of vessels similar to the lymphatics, named lacteals, to the commencement of the thoracic duct, where it is intermingled
with the lymph and poured into the circulation through the same channels. It must be borne in mind that these two sets of vessels, lymphatics and lacteals, though differing in name, are identical in structure, and that the character of the fluid they convey is different only while digestion is going on. At other times the lacteals convey a transparent, nearly colorless fluid not to be distinguished from lymph. Both these sets of vessels, in their passage to the central duct, pass through certain small glandular bodies, termed lymphatic glands, where their contents perhaps undergo elaboration.

Lymph, as its name implies, is a watery fluid. It closely resembles the liquor sanguinis, and contains about 5 per cent. of albumen and 1 per cent. of salts. When examined under the microscope, it is found to consist of a clear colorless fluid, in which are floating a number of corpuscles, lymph-corpuscles. These bodies are identical in structure, and not to be distinguished from the white blood-corpuscles previously described. They vary in number in different parts of the lymphatic vessels, and indeed are said by Kölliker to be absent in the smaller ones. They are always increased in number after the passage of the lymph through a lymphatic gland, and are said to be increased in size as the fluid ascends higher in the course of the circulation.

Chyle is a milk-white fluid, which exactly resembles lymph in its physical and chemical properties, except that it has, in addition to the other constituents of lymph, an enormous amount of fatty granules, "the molecular basis of chyle," and it is to the presence of these molecules that chyle owes its milky color. Under the microscope it presents a number of corpuscles, named "chyle-corpuscles," which are indistinguishable from lymph-corpuscles or white blood-cells, and the molecular basis, consisting principally of fatty granules of extreme minuteness (Fig. 5, a), but also of a few small oil-globules. Lymph and chyle after their passage through their respective glands, if withdrawn from the body and allowed to stand, separate more or less completely into a clear liquid, which is identical with the serum of the blood, and a thin jelly-like clot, consisting of a fibrillated matrix in which lymph-corpuscles or chyle-corpuscles and fatty molecules, as the case may be, are entangled.

If the contents of the thoracic duct are examined, especially after a meal, there may be found in it corpuscles with a reddish tinge. These have been regarded, probably erroneously, as immature red corpuscles, or lymph- and chyle-corpuscles in process of transformation into blood-globules. They frequently give to the surface of clotted chyle and lymph a pinkish hue. They must not be mistaken for mature blood-globules, which are sometimes found in lymph and chyle, and which are regarded by most observers as accidental—i. e. produced by the manipulations of the dissector.

**THE ANIMAL CELL.**

All the tissues and organs of which the body is composed were originally developed from a microscopic body (the ovum), consisting of a soft gelatinous granular material enclosed in a membrane, and containing a vesicle, or small spherical body, inside which are one or more solid spots (see Fig. 73). This may be regarded as a perfect cell. Moreover, all the solid tissues can be shown to consist largely of similar bodies, differing, it is true, in external form, but essentially similar to an ovum. These are also cells.

In the higher organisms all such cells may be defined as "nucleated masses of protoplasm of microscopic size." The two essentials, therefore, of an animal cell in the higher organisms are, the presence of a soft gelatinous granular material,
similar to that found in the ovum, and which is usually styled protoplasm; and a small spherical body imbedded in it, and termed a nucleus; the remaining constituents of the ovum—viz. its limiting membrane and the solid spot contained in the nucleus, called the nucleolus—are not considered essential to the cell, and in fact many cells exist without them.

Protoplasm (sarcode, blastema, germinal matter, or bioplasin) is a proteid compound. It also contains certain inorganic substances, as phosphorus and calcium, which latter appears to be essential to its life and function. It is of a semi-fluid, viscid consistence, and appears, sometimes, either as a hyaline substance, homogeneous and clear, or as a granular substance, consisting of minute molecules imbedded in a transparent matrix. These molecules are regarded by some as adventitious material taken in from without, and often probably of a fatty nature, since they are frequently soluble in ether. In most cells, however, protoplasm shows a more definite structure, consisting of minute striæ or fibrils arranged in a clear transparent matrix, or a honeycombed reticulum containing in its interstices a homogeneous substance. Protoplasm is insoluble in water, coagulates at 130° F., and has a great affinity for certain staining reagents, as logwood or carmine.

The most striking characteristics of protoplasm are its vital properties of motion and nutrition. By motion is meant the power which protoplasm has of changing its shape and position by some internal power in itself, which enables it to thrust out from its main body an irregular process, into which the whole of the protoplasmic substance is gradually drawn, so that the mass comes to occupy a new position. This, on account of its resemblance to the movements observed in the Amœba or Proteus animalcule, has been termed "amoeboid movement." Ciliary movement, or the vibration of hair-like processes from the surface of any structure, may also be regarded as a variety of the motion with which protoplasm is endowed. Nutrition is the power which protoplasm has of attracting to itself the materials of growth from surrounding matter. When any foreign particle comes in contact with the protoplasmic substance, it becomes incorporated in it by being enwrapped by one or more processes projected from the parent mass and enclosed by them. When thus taken up, it may remain in the substance of the protoplasm for some time without change, or may be assimilated by the protoplasm.

The Nucleus is a minute body, imbedded in the protoplasm, and usually of a spherical or oval form, its size having little relation to the size of the cell. It is usually surrounded by a well-defined wall, the nuclear membrane, and its contents, known as the nuclear substance, are composed of a stroma or network and an interstitial substance, the relative amount of the two varying in different nuclei. The network appears to be continuous through the nuclear membrane with the protoplasmic reticulum, from which it differs, however, in having strung along it bands of a substance which stains readily with certain dyes, and is therefore named chromatin. The chromatin differs chemically from ordinary protoplasm in containing nuclein, in its power of resisting the action of acids and alkalis, in its imbibing more intensely the stain of carmine, haematoxylin, etc., and in its remaining unsustained by some reagents which color ordinary protoplasm; as, for example, nitrate of silver.

The process of reproduction of cells commences in the nucleus, and is usually described as being brought about by indirect or by direct division. Indirect division or karyokinesis (karyomitiōsis) has been observed in all the tissues—generative cells, epithelial tissue, connective tissue, muscular tissue, and nerve-tissue—and it is the typical method by which the division of cells takes place, although the process of reproduction of cells by direct division occurs not infrequently, especially in highly specialized cells.

The process of reproduction by indirect division commences in the nucleus, the stroma of which undergoes complex changes, leading to the division of this body previous to the cleavage of the protoplasm of the cell. The changes consist briefly of the following: (1) At the commencement of the process the nuclear network is
well developed, but shows only slight indications of activity. (2) The chromatic fibrils, after rearranging themselves, become thicker, and probably combine in one long filament, which forms a loose convolution. This is called the glomerulus or skein (Fig. 6, b). At the same time a number of protoplasmic granules arrange themselves at two points in the cell-protoplasm opposite each other; these points are called the poles, and the line midway between them, and bisecting at right angles a line connecting the two, is called the equator. The aggregations of protoplasmic granules are termed the centrosomes, and they are surrounded by clear protoplasmic areas known as the archoplasm spheres. (3) The chromatic
filament becomes arranged in more or less distinct loops converging toward the two poles, resembling somewhat in appearance a "rosette or wreath (Fig. 6, c). From the poles to the loops, fine threads, not staining like the others (achromatic), are seen bridging across the space left between the filament and the cell-protoplasm. These are known as the nuclear spindle. (4) The loops now become flattened so as to form a festooned ring or star at the equator of the nucleus. This is known as the single star, aster, monaster. The loops begin to break transversely at the equator (Fig. 6, d*), having sometimes previously broken at their polar ends. The nuclear spindle or achromatin is very distinct, as well as a radiating arrangement of protoplasmic granules toward the poles. It is at this stage, or sometimes after, that a longitudinal splitting of the filaments occurs, so that they become more numerous and more slender. (5) After breaking across at the equator, the chromatic filaments move toward the poles as if they were guided by the achromatic threads. These threads bridge across between the two receding stars, which are known as diaster or daughter stars. The protoplasm, with its radiating granules, begins to group itself around the two poles (Fig. 6, e). (6) The daughter stars have now reached the poles; the broken ends become united, so that each daughter chromatic filament becomes a single festooned filament, forming a rosette or wreath, the daughter rosettes or wreaths. There is now distinct evidence of cleavage in the protoplasm (Fig. 6, f). (7) By further irregular contraction the regular arrangement of the loops becomes lost, and the filament presents a convoluted appearance, constituting the daughter glomeruli or skeins (Fig. 6, g). The cleavage of the protoplasm is now complete except where the achromatic threads are found. (8) By further convolution and contraction the loops of the filament become fused together, and form again a network. The nuclear membrane which disappeared at the beginning of the karyokinesis is formed anew, and two daughter cells with nuclei are formed (Fig. 6, h). The remains of the achromatic threads bridge across the intercellular substance, but later usually disappear completely.

In the reproduction of cells by direct division the process is brought about either by segmentation or by gemmation. In reproduction by segmentation or fission the nucleus first splits by becoming constricted in its centre, and thus assuming an hour-glass shape. This leads to a cleavage or division of the whole protoplasmic mass of the cell; and thus we find that two new cells have been formed, consisting of the same substance as the original one, and each containing a nucleus. These daughter cells are of course at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may rapidly take place. In reproduction by gemmation a budding-off or separation of a portion of the nucleus and parent-cell takes place, and, becoming separated, forms a new organism.

The cell-wall, which is not an essential constituent, and in fact is often absent, consists of a flexible, transparent, structureless or finely striated membrane, which is permeable to fluids. As far as is known, every animal cell is derived from a pre-existing cell. The death of cells is accomplished either by their mechanical detachment from the surface, preceded possibly by their bursting and discharging their contents, or by various forms of degeneration—fatty, pigmentary, or calcareous.

**EPITHELIUM.**

All the surfaces of the body—the external surface of the skin, the internal surface of the digestive, respiratory, and genito-urinary tracts, the closed serous cavities, the inner coat of the vessels, and the ducts of all secreting and excreting glands—are covered by one or more layers of simple cells, called epithelium or epithelial cells. These cells are also present in the sensory and terminal parts of the organs of special sense, and in some other organs, as the pituitary and thyroid bodies. They serve various purposes, forming in some cases a protective layer, in others acting as an agent in secretion and excretion, and again in others being concerned in the elaboration of the organs of special sense. Thus, in the skin,
the main purpose served by the epithelium (here called the epidermis) is that of protection. As the surface is worn away by the agency of friction or change of temperature new cells are supplied, and thus the surface of the true skin and the vessels and nerves which it contains are defended from damage. In the gastro-intestinal mucous membrane and in the glands the epithelial cells appear to be the principal agents in separating the secretion from the blood or from the alimentary fluids. In other situations (as the nose, fauces, and respiratory passages) the chief office of the epithelial cells appears to be to maintain an equable temperature by the moisture with which they keep the surface always slightly lubricated. In the serous cavities they also keep the opposed layers moist, and thus facilitate their movements on each other. Finally, in all internal parts they ensure a perfectly smooth surface.

Of late years there has been a tendency on the part of many histologists to divide these several epithelial linings into two classes: into (1) epithelial tissue proper, consisting of nucleated protoplasmic cells, which form continuous masses on the skin and mucous surfaces and the linings of the ducts and alveoli of secreting and excreting glands; and (2) endothelium, which is composed of a single layer of flattened transparent squamous cells, joined edge to edge in such a manner as to form a membrane of cells. This is found on the free surfaces of the serous membranes, as the lining membrane of the heart, blood-vessels, and lymphatics; on the surface of the brain and spinal cord, and in the anterior chamber of the eye. And, though the separation must be an artificial one, since every gradation of transition between the two classes may be observed, it would seem advisable for the purpose of description to employ it.

1. True epithelial tissue consists of one or more layers of cells, united together by an interstitial cement-substance, supported on a basement-membrane, and is naturally grouped into two classes, according as there is a single layer of cells (simple epithelium) or more than one (stratified epithelium). The various kinds of epithelium, whether arranged in a single layer or in more than one layer, are usually spoken of as squamous or pavement, columnar, spheroidal or glandular, and ciliated.

The pavement epithelium (Fig. 7) is composed of flat nucleated scales of various shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal. The flattening depends upon the thinness of the cell. The protoplasm of the cell presents a fine reticulum or honeycombed network, which gives to the cell the appearance of granulation. This kind of epithelium is found on the surface of the skin (epidermis) and on mucous surfaces which are subjected to friction. The nails, the hairs, and (in animals) the horns are a variety of this kind of epithelium.

A variety of squamous epithelium which is found in the deeper layers of
stratified pavement epithelium has been termed *prickle cells*. These cells possess short fine fibrils which pass from their margins to those of neighboring cells, serving to connect them together. They were first probably noticed by Max Schultze and Virchow, and it was believed that by them the cells were dovetailed together. Subsequently this was shown not to be so by Bizzozero, who pointed out that the prickles were attached to each other by their apices and formed minute bridges across spaces occurring between the cells of the epithelium.

The *columnar* or *cylindrical* epithelium (Fig. 8) is formed of cylindrical or rod-shaped cells, each containing a nucleus, and set together so as to form a complete membrane. The cells have a prismatic figure, more or less flattened from mutual pressure, and are set upright on the surface on which they are supported. Their protoplasm is always more or less longitudinally striated, and they contain a nucleus which is oval in shape and contains an intranuclear network.

This form of epithelium covers the mucous membrane of nearly the whole gastro-intestinal tract and the glands of that part, the greater part of the urethra, the vas deferens, the prostate, Cowper's glands, Bartholini's glands, and a portion of the uterine mucous membrane.

*Goblet- or chalice-cells* are a modification of the columnar cell. They appear to be formed by an alteration in shape of the columnar epithelium (ciliated or otherwise) consequent on the secretion into the interior of the cell of *mucin*, the chief organic constituent of mucus, which distends the upper part of the cell, while the nucleus is pressed down toward its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane, as shown in Fig. 9.

The *spheroidal* or *glandular* epithelium (Fig. 10) is composed of circular or polyhedral cells. Like other forms of epithelial cells, the protoplasm is a fine reticulum, which gives to the cell the appearance of granulation. They are found in the terminal recesses of secreting glands, and the protoplasm of the cells usually contains the materials which the cells secrete.

*Ciliated* epithelium (Fig. 11) may be of any of the preceding forms, but usually
inclines to the columnar shape. It is distinguished by the presence of minute processes, which are direct prolongations of the cell-protoplasm standing up from the free surface like hairs or eyelashes (cilia). If the cells are examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in tepid water, the cilia will be seen in lashing motion; and if the cells are separate, they will often be seen to be moved about in the field by that motion.

The situations in which ciliated epithelium is found in the human body are: the respiratory tract from the nose downward (except over the lower portion of the pharynx and the surface of the vocal cords) the tympanum and Eustachian tube, the Fallopian tube and upper portion of the uterus, the vasa efferentia, coni vasculosi, and first part of the excretory duct of the testicle, and the ventricles of the brain and central canal of the spinal cord.

Stratified epithelium consists of several layers of cells superimposed one on the top of the other and varying greatly in shape. The cells of the deepest layer are for the most part columnar in form, and as a rule form a single layer, placed vertically on the supporting membrane; above these are several layers of spheroidal cells, which as they approach the surface become more and more compressed, until the superficial layers are found to consist of flattened scales, the margins of which overlap one another, so as to present an imbricated appearance. Another form of stratified epithelium is found in what has been termed transitional epithelium, such as exists in the ureters and urinary bladder. Here the cells of the most superficial layer are cubical, with depressions on their under surfaces, which fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement-membrane. Between their tapering points is a third variety of cells, filling in the intervals between them, and of smaller size than those of the other two layers.

2. Endothelium.—As before stated, endothelial cells are flattened, transparent, squamous cells, attached by their margins by a semi-fluid homogeneous cement-substance, so as to form a continuous endothelial membrane. Though for the most part these cells are squamous, in some places cells may be found, either isolated or occurring in patches, which are polyhedral or even columnar. These latter cells are frequently to be found lining the stomata of serous membranes (Fig. 12). As a rule, the endothelial cells are polygonal in outline, with sinuous or jagged margins, and are in close apposition, the amount of cohesive matter uniting them being so slight as not to be apparent. Their protoplasmic substance appears to be granular, but consists of fibrillae arranged in a network in which the nucleus is contained, limited by a membrane and having a well-developed reticulum.

CONNECTIVE TISSUES.

By the term connective tissue we mean a number of tissues which possess this feature in common—viz. that they serve the general purpose in the animal economy
of supporting and connecting the tissues of the frame. These tissues may differ considerably from each other in external appearance, but they present nevertheless many points of relationship with each other, and are moreover developed from the same embryonal elements. They are divided into three great groups: (1) the fibrous connective tissues, (2) cartilage, and (3) bone.

The Fibrous Connective Tissues.—Three principal forms or varieties of fibrous connective tissue are recognized: (1) White fibrous tissue; (2) Yellow elastic tissue; (3) Areolar tissue. They are all composed of a matrix in which cells are imbedded, and between the cells are fibres of two kinds, the white and yellow or elastic. The difference between the three forms of tissue depends on the relative proportion of the two kinds of fibre, in the first variety enumerated the white fibre preponderating; in the second variety the yellow elastic fibres being greatly in excess of the white; and the third form, areolar tissue, the two being blended in much more equal proportions.

The white fibrous tissue (Fig. 13) is a true connecting structure, and serves three purposes in the animal economy. It serves to bind bones together in the form of ligaments, it serves to connect muscles to bones or other structures in the form of tendons, and it forms an investing or protecting structure to various organs in the form of membranes. Examples of where it serves this latter office are to be found in the muscular fascia or sheaths, the perios- teum, and perichondrium; the investments of the various glands, (such as the tunica albuginea testis, the capsule of the kidney, etc.), the investing sheath of the nerves (epineurium), and of various organs, as the penis and the eye (sheath of the corpora cavernosa and corpus spongiosum, and of the sclerotic). But in all these parts the student must bear in mind that the elastic tissue enters in greater or less proportion. It presents to the naked eye the appearance of silvery-white glistening fibres, covered over with a quantity of loose, flocculent tissue which binds the fibres together and carries the blood-vessels. It is not possessed of any elasticity, and only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external violence the bone with which it is connected will fracture before the fibrous tissue will give way. When examined under the microscope it is found to consist of waving bands or bundles of minute, transparent, homogeneous filaments or fibrillae, held together by an albuminous semi-fluid cement-substance (Fig. 14). In ligaments and tendons these bundles run parallel with each other; in membranes they intersect one another in different places. The bundles have a tendency to split up longitudinally or send off slips to join other bundles and receive others in return. The cells occurring in white fibrous tissue are often called "tendon cells." They are situated on the surface of groups of bundles and are quadrangular in shape, arranged in rows in single file, each cell being separated from its neighbors by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining cell being in close proximity to it (Fig. 15). Upon the addition of acetic acid to white fibrous tissue it swells up into a glassy-looking, indistinguishable mass. When boiled in water it is converted almost completely into gelatin.

Yellow Elastic Tissue.—In certain parts of the body a tissue is found which when viewed in mass is of a yellowish color, and is possessed of great elasticity, so that it is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is yellow elastic tissue, in
which the elastic fibres greatly preponderate, to the almost complete exclusion of the white fibrous element. It is found in this condition in the ligamenta subflava, in the vocal cords, in the longitudinal coat of the trachea and bronchi, in the inner coats of the blood-vessels, especially the larger arteries, and to a very con-

![Fig. 14—Connective tissue. (Klein and Noble Smith.) a. The white fibrous element—a layer of more or less sharply-outlined, parallel, wavy bundles of connective-tissue fibrils. On the surface of this layer is b, a network of fine elastic fibres.

Fig. 15.—Tendon of mouse’s tail, stained with hematoxylin, showing chains of cells between the tendon-bundles. (From Quain’s Anatomy. E. A. Schafer.)

siderable extent in the thyro-hyoid, crico-thyroid, and stylo-hyoid ligaments. It is also found in the ligamentum nuchae of the lower animals. When viewed under the microscope (Fig. 16) it is seen to consist of an aggregation of curling fibres, with a well-defined outline. They are considerably larger in size than the fibrille of the white fibrous element, and vary much, being from the $\frac{1}{24000}$ to the $\frac{1}{4000}$ of an inch in diameter. The fibres form bold and wide curves, branch and freely anastomose with each other. They are homogeneous in appearance, and have a tendency to curl up, especially at their broken ends. In some parts, where the fibres are broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding to the intervening space. This is to be found in the inner coat of the arteries, and to it the name of fenestrated membrane has been given by Henle. The yellow elastic fibres remain unaltered by acetic acid.

\[\text{Arcolar tissue}\] is so called because its meshes are easily distended, and thus separated into areoles or spaces, which all open freely into each other, and are consequently easily blown up with air, or permeated by fluid when injected into any part of the tissue. Such spaces, however, do not exist in the natural condition of the body, but the whole tissue forms one unbroken membrane composed of a number of interlacing fibres, variously superimposed. Hence the term “the cellular membrane” is in many parts of the body more appropriate than its more modern equivalent. The chief use of the areolar tissue is to bind parts together, while by the laxity of its fibres and the permeability of its areole it allows them to move on each other, and affords a ready exit for inflammatory and other effused fluids. It is one of the most extensively distributed of all the tissues in the body. It is found beneath the skin in a continuous layer all over the body, connecting it to the subjacent parts. In the same way it is situated beneath the mucous and serous membranes. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. In addition to this, it is found in the interior of organs, binding together the various lobes and lobules of the compound glands,
the various coats of the hollow viscera, and the fibres of muscles, etc., and thus forms one of the most important connecting media of the various structures or organs of which the body is made up. In many parts the areolae or interspaces of areolar tissue are occupied by fat-cells, constituting adipose tissue, which will presently be described.

Areolar tissue presents to the naked eye a flocculent appearance, somewhat like spun silk. When stretched out, it is seen to consist of delicate soft elastic threads interlacing with each other in every direction and forming a network of extreme delicacy. When examined under the microscope it is found to be composed of white fibres and elastic fibres intercrossing in all directions, and united together by a homogeneous cement or ground-substance, and filled by cellular elements, which contain the protoplasm out of which the whole is developed and regenerated.

These cell-spaces may be brought into view by treating the tissue with nitrate of silver, and exposing it to the light. This will color the fibres and ground-substance, leaving the cell-spaces unstained.

The cells of areolar tissue (Fig. 17) are of two kinds: 1, flattened transparent cells, with an oblong nucleus and more or less branched, and often united together by thin-branched processes; and 2, granular cells, some of which are of the size
of white blood-corpuscles, and like them possessed of amoeboid movements; others are of larger size, and do not exhibit amoeboid movements to any appreciable extent. They lie imbedded in the ground-substance, and in some situations, where the areolar tissue is loose and the spaces large, so as to contain several cells, they form a sort of lining for it. In other situations where the tissue forms a membranous layer, the flattened cells, here unbranched, form an epithelial-like covering to its surface.

**Vessels and Nerves of Connective Tissue.***—The blood-vessels of connective tissue are very few—that is to say, there are few actually destined for the tissue itself, although many vessels may permeate one of its forms, the areolar tissue, carrying blood to other structures. In white fibrous tissue the blood-vessels usually run parallel to the longitudinal bundles and between them, sending transverse communicating branches across, and in some forms, as the periosteum and dura mater, being fairly numerous. In the yellow elastic tissue the blood-vessels also run between the fibres, and do not penetrate them. Lymphatic vessels are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and the serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves. Nerves are to be found in the white fibrous tissue, where they terminate in a special manner; but it is doubtful whether any nerves terminate in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

**Development of Connective Tissue.***—Fibrous connective tissue is developed from embryonic connective-tissue cells derived from the mesoblast. At an early period of development it consists of nucleated cells and a mucoid-albuminous fluid, which subsequently becomes a pellucid jelly and forms the ground-substance. In this ground-substance the two varieties of fibres become developed. As to the manner in which they do so there are two theories, some believing that they are developed from the protoplasm of the cells, others that they are formed by a deposit in the ground-substance. In the former case the protoplasm of the cells is converted wholly into elementary fibres, the nucleus disappearing; or else the peripheral part of the protoplasm produces the fibrous tissue, the original cell growing again to its original size, and then throwing off a fresh portion to form a new cell, and itself persisting in contact with the fibres it has formed as a permanent connective-tissue corpuscle.

Three special forms of connective tissue must be described: the mucoid, the lymphoid or retiform, and basement-membranes.

1. The **mucoid** or **gelatinous** connective tissue exists chiefly in the “jelly of Wharton,” which forms the bulk of the umbilical cord, but is also found in some other situations in the fetus, as in the pulp of young teeth, and in certain stages of the development of connective tissue in various regions. In the adult the vitreous humor of the eye is formed of the same material. This tissue consists of nucleated cells, which branch and become connected so as to form trabeculae, which traverse a jelly-like ground substance, containing the chemical principle of mucus, or mucin, and in smaller quantities albumen, but no gelatin. Sometimes, as in the vitreous humor of the eye, the cells almost completely disappear and the jelly only remains.

2. **Retiform** connective tissue (Fig. 18) is found extensively in many parts of the body, forming the framework of some organs and entering into the construction of many mucous membranes. It is formed of an interlacement or network of very fine fibres, which closely resemble white fibrous tissue, and in certain situations may be demonstrated to be continuous with it. In their behavior to certain reagents, however, they differ from the ordinary white fibres, and have consequently been held to be a third form of connective-tissue fibres. In many places flattened cells may be seen connected with the fibres and partially concealing them, presenting an appearance as if the tissue were formed of a network of branching and anastomosing cells. This, however, is not so, as the cells can be removed or
brushed away, leaving the fibres intact. In many situations the interstices of the fibres are filled with rounded granular corpuscles, and the tissue is then termed lymphoid or adenoid tissue. The neuroglia, or fine gelatinous connective tissue which supports the nervous elements in the cerebro-spinal axis and in the retina has been regarded as a modified form of the retiform connective tissue. It is now known, however, to consist of cells which send off very numerous fine processes, and develop from the epiblast, certain of the cells forming the wall of the medullary canal, becoming neuroglia cells, while the remainder become nerve-cells.

3. Basement-membranes. formerly described as homogeneous membranes, are really a form of connective tissue. They constitute the supporting membrane, or membrana propria, supporting the epithelium of mucous membranes or secreting glands, and in other situations. By means of staining with nitrate of silver they may be shown to consist of flattened cells in close apposition, and form therefore an example of an epithelioid arrangement of connective-tissue cells. In some situations the cells, instead of adhering by their edges, give off branching processes, which join with similar processes of other cells, and so form a network rather than a continuous membrane.

Adipose Tissue.—In almost all parts of the body the ordinary areolar tissue contains a variable quantity of adipose or fatty tissue. The principal situations where it is not found are the subcutaneous tissue of the eyelids, the penis and scrotum, the nymphae, within the cavity of the cranium, and in the lungs, except near the roots. Nevertheless, its distribution is not uniform, in some parts being collected in great abundance, as in the subcutaneous tissue, especially of the abdomen; around the kidneys; on the surface of the heart between the furrows; and in some other situations. Lastly, fat enters largely into the formation of the marrow of bones. A distinction must, however, be made between fat and adipose tissue; the latter being a distinct tissue, the former an oily matter, which
in addition to its occurrence in adipose tissue is also widely present in the body, as in the fat of the brain and liver and in the blood and chyle, etc.

Fat-cells (Fig. 19) consist of a number of vesicles, varying in size, but of about the average diameter of \( \frac{1}{40} \) of an inch. They are formed of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but becomes solidified after death. They are round or spherical where they have not been subjected to pressure; otherwise they assume a more or less angular outline. A nucleus is always present, and can be easily demonstrated by staining with hematoxylin; in the natural condition it is so compressed by the contained oily matter as to be scarcely recognizable. These fat-cells are contained in clusters in the areola of fine connective tissue, and are held together mainly by a network of capillary blood-vessels, which are distributed to them.

Fat is an inorganized substance, consisting of a liquid material (glycerin) in combination with certain fatty acids, stearic, palmitic, and oleic. Sometimes the acids separate spontaneously before the fat is examined, and are seen under the microscope in a crystalline form, as in Fig. 19, a. By boiling the tissue in ether or strong alcohol the fat may be extracted from the vesicle, which is then seen empty and shrunken.

Fat is said to be first detected in the human embryo about the fourteenth week. The fat-cells are formed by the transformation of the protoplasmic connective-tissue corpuscles, into which small globules of fat find their way, and increase until they distend the corpuscle into the thin mantle of protoplasm which forms the cell-wall, and in which its nucleus is still to be seen (Fig. 20).

PIGMENT.

In various parts of the body pigment is found; most frequently in epithelial cells and in the cells of connective tissue. Pigmented epithelial cells are found forming the external layer of the retina (Fig. 21) and on the posterior surface of the iris. Pigment is also found in the epithelial cells of the deeper layers of the cuticle in some parts of the body—such as the areola of the nipple and in colored patches of skin, and especially in the skin of the colored races, and also in hair. It is also found in the epithelial cells of the olfactory region and of the membranous labyrinth of the ear.

In the connective-tissue cells pigment is frequently met with in the lower vertebrates. In man it is found in the choroid coat of the eye, and in the iris of all but the light-blue eyes and the albino. It is also occasionally met with in the cells of retiform tissue and in the pia mater of the upper part of the spinal cord. These cells are characterized by their larger size and branched processes, which, as well as the body of the cells, are filled with granules. The pigment consists of dark-brown or black granules of very small size, closely packed together within the cells, but not invading the nucleus. Occasionally the pigment is yellow, and when occurring in the cells of the cuticle constitutes "freckles."
CARTILAGE.

Cartilage is a non-vascular structure which is found in various parts of the body—in adult life chiefly in the joints, in the parietes of the thorax, and in various tubes, such as the air-passages, nostrils, and ears, which are to be kept permanently open. In the fetus at an early period the greater part of the skeleton is cartilaginous. As this cartilage is afterward replaced by bone, it is called temporary, in contradistinction to that which remains unossified during the whole of life, and which is called permanent.

Cartilage is divided, according to its minute structure, into true or hyaline cartilage, fibrous or fibro-cartilage, and yellow or elastic or reticular cartilage. Besides these varieties met with in the adult human subject, there is a variety called cellular cartilage, which consists entirely, or almost entirely, of cells, united in some cases by a network of very fine fibres, in other cases apparently destitute of any intercellular substance. This is found in the external ear of rats, mice, and some other animals, and is present in the chorda dorsalis of the human embryo, but is not found in any other human structure. The various cartilages in the body are also classified, according to their function and position, into articular, interarticular, costal, and membraniform.

Hyaline cartilage, which may be taken as the type of this tissue, consists of a gristly mass of a firm consistence, but of considerable elasticity and of a pearly-blush color. Except where it coats the articular ends of bones, it is enveloped in a fibrous membrane, the perichondrium, from the vessels of which it imbibes its nutritive fluids, being itself destitute of blood-vessels; nor have any nerves been traced into it. Its intimate structure is very simple. If a thin slice is examined under the microscope, it will be found to consist of cells of a rounded or bluntly angular form, lying in groups of two or more in a granular or almost homogeneous matrix (Fig. 22). The cells, when arranged in groups of two or more, have generally a straight outline where they are in contact with each other, and in the rest of their circumference are rounded. The cell-contents consist of clear translucent protoplasm containing minute granules, and imbedded in this are one or two nuclei, having usually a granular appearance, but occasionally being clear and occupied by one or more nucleoli. The cells are imbedded in cavities in the matrix, called cartilage lacunae, which are lined by a distinct transparent membrane called the capsule. Each lacuna is generally occupied by a single cell, but during the division of the cells it may contain two, four, or eight cartilage-cells. By boiling the cartilage for some hours and treating it with concentrated mineral acid, the capsule may be freed from the matrix, and can then be demonstrated as a distinct vesicle containing the cells. By exposure to the action of an electric shock the cell assumes a jagged outline and shrinks away from the interior of the capsule.

The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. Some observers have shown that the matrix of hyaline cartilage, and especially the articular variety, after prolonged maceration, can be broken up into fine fibrils. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the lacunae with each other, and that these canals communicate with the lymphatics of the perichondrium, and thus the structure is permeated with a current of nutritious fluid.
The articular cartilages, the temporary cartilages, and the costal cartilages are all of the hyaline variety. They present minute differences in the size and shape of their cells and in the arrangement of their matrix. In the articular cartilages, which show no tendency to ossification, the matrix is finely granular under a high power; the cells and nuclei are small and are disposed parallel to the surface in the superficial part, while nearer to the bone they become vertical. Articular cartilages have a tendency to split in a vertical direction, probably from some peculiarity in the intimate structure or arrangement of the component parts of the matrix. In disease this tendency to a fibrous splitting becomes very manifest. Articular cartilage is not covered by perichondrium, at least on its free surface, where it is exposed to friction, though a layer of connective tissue can be traced in the adult over a small part of its circumference continuous with that of the synovial membrane, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective-tissue corpuscles of the synovial membrane.

Articular cartilage forms a thin incrustation upon the joint-surfaces of the bones, and its elasticity enables it to break the force of any concussion, whilst its smoothness affords ease and freedom of movement. It varies in thickness according to the shape of the bone on which it lies; where this is convex the cartilage is thickest at the centre, where the greatest pressure is received; and the reverse is the case on the concave surfaces of the bones. Articular cartilage appears to imbibe its nutrient partly from the vessels of the neighboring synovial membrane, partly from those of the bone upon which it is implanted. Mr. Toynbee has shown that the minute vessels of the cancellous tissue as they approach the articular lamella dilate and form arches, and then return into the substance of the bone.

In the costal cartilages the cells and nuclei are large, and the matrix has a tendency to fibrous striation, especially in old age (Fig. 23). These cartilages are also very prone to ossify. In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears at first sight an exception to the statement that cartilage is a non-vascular tissue, but is not so really, for the vessels give no branches to the cartilage-substance itself, and the channels may rather be looked upon as involutions of the perichondrium. The ensiform cartilage may be regarded as one of the costal cartilages, and the cartilages of the nose and of the larynx and trachea resemble them in microscopic characters, except the epiglottis and cornicular laryngis, which are of the cartilaginous variety.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, to have their matrix permeated by the salts of lime without any appearance of true bone. The process of calcification occurs also and still more frequently, according to Rollett, in such cartilages as those of the trachea, which are prone afterward to conversion into true bone.

White fibro-cartilage consists of a mixture of white fibrous tissue and cartilaginous tissue in various proportions; it is to the first of these two constituents that its flexibility and toughness are chiefly owing, and to the latter its elasticity. When examined under the microscope it is found to be made up of fibrous connective tissue arranged in bundles, with cartilage-cells between the bundles; these
to a certain extent resemble tendon-cells, but may be distinguished from them by being surrounded by an investing capsule and by their being less flattened (Fig. 24). The fibro-cartilages admit of arrangement into four groups—interarticular, connecting, circumferential, and stratiform.

The interarticular fibro-cartilages (menisci) are flattened fibro-cartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, thinner toward their centre than at their circumference, and held in position by their margins and extremities being connected to the surrounding ligaments. The synovial membrane of the joint is prolonged over them a short distance from their attached margins. They are found in the temporo-maxillary, sterno-clavicular, acromio-clavicular, wrist and knee-joints. These cartilages are usually found in those joints which are most exposed to violent concussion and subject to frequent movement. Their use is—to maintain the apposition of the opposed surfaces in their various motions; to increase the depth of the articular surfaces and give ease to the gliding movement; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these interarticular fibro-cartilages serve an important purpose in increasing the variety of movements in a joint. Thus, in the knee-joint there are two kinds of motion,—viz. angular movement and rotation, although it is a hinge joint, in which, as a rule, only one variety of motion is permitted; the former movement taking place between the condyles of the femur and the interarticular cartilage, the latter between the cartilage and the head of the tibia. So, also, in the temporo-maxillary joint, the upward and downward movement of opening and shutting the mouth takes place between the cartilage and the jaw-bone, the grinding movement between the glenoid cavity and the cartilage, the latter moving with the jaw-bone.

The connecting fibro-cartilages are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebrae and between the pubic bones. They form disks, which adhere closely to both of the opposed bones, and are composed of concentric rings of fibrous tissue, with cartilaginous laminae interposed, the former tissue predominating toward the circumference, the latter toward the centre.

The circumferential fibro-cartilages consist of a rim of fibro-cartilage, which surrounds the margin of some of the articular cavities, as the cotyloid cavity of the hip and the glenoid cavity of the shoulder; they serve to deepen the articular surface and to protect the edges of the bone.

The stratiform fibro-cartilages are those which form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibro-cartilage are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the peroneus longus and the tibialis posterior.

Yellow, or reticular, elastic cartilage is found in the human body in the antricle of the external ear, the Eustachian tubes, the cornicula laryngis, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded in every direction, except immediately around each cell, by a network of yellow.
elastic fibres, branching and anastomosing in all directions (Fig. 25). The fibres resemble those of yellow elastic tissue, both in appearance and in being unaffected by acetic acid; and according to Rollett their continuity with the elastic fibres of the neighboring tissue admits of being demonstrated.

The distinguishing feature of cartilage as to its chemical composition is that it yields on boiling a substance called chondrin, very similar to gelatin, but differing from it in not being precipitated by tannin. According to Kühne there is a small amount of gelatin in hyaline cartilage. Virchow believes that the semilunar disks in the knee-joint are wrongly denominated cartilages, since they yield no chondrin on boiling; and he appears to regard them as a modification of a tendinous structure, which, however, agrees with the cartilages in the important particular of being non-vascular.

Temporary cartilage and the process of its ossification will be described with Bone.

BONE.

Structure and Physical Properties of Bone.—Bone is one of the hardest structures of the animal body; it possesses also a certain degree of toughness and elasticity. Its color, in a fresh state, is of a pinkish white externally, and deep red within. On examining a section of any bone, it is seen to be composed of two kinds of tissue, one of which is dense and compact in texture, like ivory; the other consists of slender fibres and lamellae, which join to form a reticular structure; this, from its resemblance to lattice-work, is called cancellous. The compact tissue is always placed on the exterior of the bone; the cancellous is always internal. The relative quantity of these two kinds of tissue varies in different bones, and in different parts of the same bone, as strength or lightness is requisite. Close examination of the compact tissue shows it to be extremely porous, so that the difference in structure between it and the cancellous tissue depends merely upon the different amount of solid matter, and the size and number of spaces in each; the cavities being small in the compact tissue and the solid matter between them abundant, whilst in the cancellous tissue the spaces are large and the solid matter in smaller quantity.

Bone during life is permeated by vessels and is enclosed in a fibrous membrane, the periosteum, by means of which many of these vessels reach the hard tissue. If the periosteum is stripped from the surface of the living bone, small bleeding points are seen, which mark the entrance of the periosteal vessels; and on section during life every part of the bone will be seen to exude blood from the minute vessels which ramify in it. The interior of the bones of the limbs presents a cylindrical cavity filled with marrow and lined by a highly vascular areolar structure, called the medullary membrane or internal periosteum, which, however, is rather the areolar envelope of the cells of the marrow than a definite membrane.

The periosteum adheres to the surface of the bones in nearly every part, excepting at their cartilaginous extremities. Where strong tendons or ligaments
are attached to the bone, the periosteum is incorporated with them. It consists of two layers closely united together, the outer one formed chiefly of connective tissue, containing occasionally a few fat-cells; the inner one, of elastic fibres of the finer kind, forming dense membranous networks, which can be again separated into several layers. In young bones the periosteum is thick, and very vascular, and is intimately connected at either end of the bone with the epiphyseal cartilage, but less closely with the shaft, from which it is separated by a layer of soft blas-
tema, containing a number of granular corpuscles or "osteoblasts," in which ossification proceeds on the exterior of the young bone. Later in life the peri-
osteum is thinner, less vascular, and the osteoblasts have become converted into an epithelial layer, which is separated from the rest of the periosteum in many places by cleft-like spaces, which are supposed to serve for the transmission of lymph. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfolia-
tion or necrosis, when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

The marrow not only fills up the cylindrical cavity in the shafts of the long
bones, but also occupies the spaces of the cancellous tissue and extends into the larger bony canals (Haversian canals) which contain the blood-vessels. It differs in composition in different bones. In the shafts of adult long bones the marrow is of a yellow color, and contains, in 100 parts, 96 of fat, 1 of areolar tissue and vessels, and 3 of fluid, with extractive matter, and consists of a matrix of fibrous tissue, supporting numerous blood-vessels and cells, most of which are fat-cells, but some few are "marrow-cells." In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebrae, in the cranial diploë, and in the sternum and ribs, it is of a red color, and contains, in 100 parts, 75 of water and 25 of solid matter, consisting of albumen, fibrin, extractive matter, salts, and a mere trace of fat. The red marrow consists of a small quantity of areolar tissue, blood-vessels, and numerous cells, some few of which are fat-cells, but the great majority roundish nucleated cells, the true "marrow-cells" of Kölliker. These marrow-cells resemble in appearance the white corpuscles of the blood, though they are larger and have a relatively larger nucleus and a clearer protoplasm, but, like them, possess ameboid movements. Amongst them may be seen smaller cells (erythroblasts) which possess a slightly pinkish hue; and it has been held by Neumann that they are a transitional stage between marrow-cells and red blood-corpuscles, while others believe them to be the direct descendants of the nucleated embryonic blood-cells (see p. 127), and to be transformed into blood-
corpuscles by the loss of their nuclei.

Giant-cells (myelo-plaques, osteoclasts), large, multinucleated, protoplasmic masses, are also to be found in both sorts of adult marrow, but more particularly in red marrow. They were believed by Kölliker to be concerned in the absorption of bone matrix, and hence the name which he gave to them—osteoclasts. They excavate small shallow pits or cavities, which are named Howe's lacunae, in which they are found lying.

Vessels of Bone.—The blood-vessels of bone are very numerous. Those of the compact tissue are derived from a close and dense network of vessels ramifying in the periosteum. From this membrane vessels pass into the minute orifices in the compact tissue, running through the canals which traverse its substance. The cancellous tissue is supplied in a similar way, but by a less numerous set of larger vessels, which, perforating the outer compact tissue, are distributed to the cavities of the spongy portion of the bone. In the long bones numerous apertures may be seen at the ends near the articular surfaces, some of which give passage to the arteries of the larger set of vessels referred to; but the most numerous and largest apertures are for the veins of the cancellous tissue, which run separately from the arteries. The medullary canal in the shafts of the long bones is supplied by one large artery (or sometimes more), which enters the bone at the nutrient foramen
(situated in most cases near the centre of the shaft), and perforates obliquely the compact structure. The medullary or nutrient artery, usually accompanied by one or two veins, sends branches upward and downward to supply the medullary membrane, which lines the central cavity and the adjoining canals. The ramifications of this vessel anastomose with the arteries both of the cancellous and compact tissues. In most of the flat, and in many of the short spongy bones, one or more large apertures are observed, which transmit, to the central parts of the bone, vessels corresponding to the medullary arteries and veins. The veins emerge from the long bones in three places (Kölliker): (1) by one or two large veins, which accompany the artery; (2) by numerous large and small veins at the articular extremities; (3) by many small veins which arise in the compact substance. In the flat cranial bones the veins are large, very numerous, and run in tortuous canals in the diploic tissue, the sides of the canals being formed by a thin lamella of bone, perforated here and there for the passage of branches from the adjacent cancelli. The same condition is also found in all cancellous tissue, the veins being enclosed and supported by osseous structure and having exceedingly thin coats. When the bony structure is divided, the vessels remain patulous, and do not contract in the canals in which they are contained. Hence the constant occurrence of purulent absorption after amputation in those cases where the stump becomes inflamed and the cancellous tissue is infiltrated and bathed in pus.

Lymphatic vessels, in addition to those found in the periosteum, have been traced by Cruikshank, into the substance of bone, and Klein describes them as running in the Haversian canals.

Nerves are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said by Kölliker to be most numerous in the articular extremities of the long bones, in the vertebrae and the larger flat bones.

Minute Anatomy.—The intimate structure of bone, which in all essential particulars is identical in the compact and cancellous tissue, is most easily studied in a transverse section from the compact wall of one of the long bones after maceration, such as is shown in Fig. 26.

If this is examined with a rather low power the bone will be seen to be mapped out into a number of circular districts, each one of which consists of a central hole, surrounded by a number of concentric rings. These districts are termed Haversian systems; the central hole is an Haversian canal, and the rings around are layers of bone-tissue arranged concentrically around the central canal, and termed lamelle. Moreover, on closer examination, it will be found that between these lamelle, and therefore also arranged concentrically around the central canal, are a number of little dark specks, the lacunae, and that these lacunae are connected with each other and with the central Haversian canal by a number of fine dark lines, which radiate like the spokes of a wheel and are called canaliculi. All these structures—the concentric lamelle, the lacunae, and the canaliculi—may be seen in any single Haversian system, forming a circular district round a central, Haversian, canal. Between these circular systems, filling the irregular intervals which are left between them, are other lamelle, with their lacunae and canaliculi, running in
various directions, but more or less curved (Fig. 27). These are termed interstitial lamellæ. Again, other lamellæ, for the most part found on the surface of the bone, are arranged concentrically to the circumference of bone, constituting, as it were, a single Haversian system of the whole bone, of which the medullary cavity would represent the Haversian canal. These latter lamellæ are termed circumferential, or by some authors primary or fundamental lamellæ, to distinguish them from those laid down around the axis of the Haversian canals, which are then termed secondary or special lamellæ.

The Haversian canals, seen as round holes in a transverse section of bone at or about the centre of each Haversian system, may be demonstrated to be true canals if a longitudinal section is made, as in Fig. 29. It will then be seen that these round holes are tubes cut across, which run parallel with the longitudinal axis of the bone for a short distance, and then branch and communicate. They vary considerably in size, some being as large as \( \frac{1}{40} \) of an inch in diameter; the average size being, however, about \( \frac{3}{60} \) of an inch. Near the medullary cavity the canals are larger than those near the surface of the bone. Each canal, as a rule, contains two blood-vessels, a small artery and vein; the larger ones also contain a small quantity of delicate connective tissue, with branched cells, the processes of which communicate with the branched processes of certain bone-cells in the substance of the bone. Those canals near the surface of the bone open upon it by minute orifices, and those near the medullary cavity open in the same way into this space, so that the whole of the bone is permeated by a system of blood-vessels running through the bony canals in the centre of the Haversian systems.

The lamellæ are thin plates of bone-tissue encircling the central canal, and might be compared, for the sake of illustration, to a number of sheets of paper pasted one over another around a central hollow cylinder. After macerating a piece of bone in dilute mineral acid, these lamellæ may be stripped off in a longitudinal direction as thin films. If one of these is examined with a high power under the microscope it will be found to be composed of a finely reticular structure, presenting the appearance of lattice-work made up of very slender, transparent fibres, decussating obliquely, and coalescing at the points of intersection so as to form an exceedingly delicate network. In many places the various lamellæ may be seen to be held together by tapering fibres, which run obliquely through them, pinning or bolting them together. These fibres were first described by Sharpey, and were named by him perforating fibres.
The lacunae are situated between the lamellae, and consist of a number of oblong spaces. In an ordinary microscopic section, viewed by transmitted light, they appear as dark, oblong, opaque spots, and were formerly believed to be solid cells. Subsequently, when it was seen that the Haversian canals were channels which lodge the vessels of the part, and the canaliculi minute tubes by which the plasma of the blood circulates through the tissue, it was taught that the lacunae were hollow spaces filled during life with the same fluid, and only lined (if lined at all) by a delicate membrane. But this view appears also to be delusive. Examination of the structure of bone, when recent, led Virchow to believe that the lacunae are occupied during life with a nucleated cell, the processes from which pass down the canaliculi—a view which is now universally received (Fig. 28). It is by means of these cells that the fluids necessary for nutrition are brought into contact with the ultimate tissue of bone.

The canaliculi are exceedingly minute channels, which pass across the lamelle and connect the lacunae with neighboring lacunae and also with the Haversian canal. From this central canal a number of the canaliculi are given off, which radiate from it, and open into the first set of lacunae, arranged around the Haversian canal, between the first and second lamellae. From these lacunae a second set of canaliculi are given off, which pass outward to the next series of lacunae, and so on until they reach the periphery of the Haversian system; here the canaliculi given off from the last series of lacunae do not communicate with the lacunae of neighboring Haversian systems, but after passing outward for a short distance form loops and return to their own lacuna. Thus every part of an Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canals and traversing the canaliculi and lacunae.

The bone-cells are contained in the lacunae, which, however, they do not completely fill. They are flattened nucleated cells, which Virchow has shown are homologous with those of connective tissue. The cells are branched, and the branches, especially in young bones, pass into the canaliculi from the lacunae.

If a longitudinal section is examined, as in Fig. 29, the structure is seen to be the same. The appearance of concentric rings is replaced by that of lamelle or rows of lacunae, parallel to the course of the Haversian canals, and these canals appear like half-tubes instead of circular spaces. The tubes are seen to branch and communicate, so that each separate Haversian canal runs only a short distance. In other respects the structure has much the same appearance as in transverse sections.

In sections of thin plates of bone (as in the walls of the cells which form the cancellous tissue) the Haversian canals are absent, and the canaliculi open into the spaces of the cancellous tissue (medullary spaces), which thus have the same function as the Haversian canals in the more compact bone.

Chemical Composition.—Bone consists of an animal and an earthy part intimately combined together. The animal part may be obtained by immersing the bone for a considerable time in dilute mineral acid, after which process the bone comes out exactly the same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. If now a transverse section is made (Fig. 30), the same general arrangement of the Haversian canals, lamellae, lacunae, and canaliculi is seen, though not so plainly, as in the ordinary section.
The earthy part may be obtained separate by calcination, by which the animal matter is completely burned out. The bone will still retain its original form, but it will be white and brittle, will have lost about one-third of its original weight, and will crumble down with the slightest force. The earthy matter confers on bone its hardness and rigidity, and the animal matter its tenacity.

The animal base is often called cartilage, but differs from it in structure, in the fact that it is softer and more flexible, and that when boiled with a high pressure it is almost entirely resolved into gelatin.

The organic constituent of bone forms about one-third, or 33.3 per cent.; the inorganic matter, two-thirds, or 66.7 per cent.; as is seen in the subjoined analysis of Berzelius:

| Organic matter | Gelatin and blood-vessels | 33.30 |
| Inorganic      | Phosphate of lime          | 51.04 |
| or             | Carbonate of lime          | 11.30 |
| Earthy matter  | Phosphate of magnesia      | 1.16  |
|                | Soda and chloride of sodium| 1.20  |
|                |                            | 100.00|

Some chemists add to this about 1 per cent. of fat.

Some difference exists in the proportion between the two constituents of bone at different periods of life. In the child the animal matter predominates, whereas in aged people the bones contain a larger proportion of earthy matter, and the animal matter is deficient in quantity and quality. Hence in children it is not uncommon to find, after an injury to the bones, that they become bent or only partially broken, whereas in old people the bones are more brittle and fracture takes place more readily. Some of the diseases, also, to which bones are liable mainly depend on the disproportion between the two constituents of bone. Thus in the disease called rickets, so common in the children of the poor, the bones become bent and curved, either from the superincumbent weight of the body, or under the action of certain muscles. This depends upon some defect of nutrition by which bone becomes deprived of its normal proportion of earthy matter, whilst the animal matter is of unhealthy quality. In the vertebrae of a rickety subject Dr. Bostock found in 100 parts 79.75 animal and 20.25 earthy matter.

**Development of Bone.**—In the foetal skeleton some bones, such as the long bones of the limbs, are cartilaginous; others, as the cranial bones, are membranous. Hence two kinds of ossification are described: the *intracartilaginous* and the *intramembranous*; and to these a third is sometimes added, the *subperiosteal*; this, however, is the same as the second, only taking place under different circumstances.
Intracartilaginous Ossification.—Just before ossification begins the bone is entirely cartilaginous, and in a long bone, which may be taken as an example, the process commences in the centre and proceeds toward the extremities, which for some time remain cartilaginous. Subsequently a similar process commences in one or more places in those extremities and gradually extends through it. The extremity does not, however, become joined to the shaft of the bone until growth has ceased, but remains separated by a layer of cartilaginous tissue termed epiphysial cartilage.

The first step in the ossification of the cartilage is that the cartilage-cells, at the point where ossification is commencing and which is termed a centre of ossification, enlarge and arrange themselves in rows (Fig. 31). The matrix in which they are imbedded increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material now takes place in this matrix, between the rows of cells, so that they become separated from each other by longitudinal columns of calcified matrix, presenting a granular and opaque appearance. Here and there the matrix between two cells of the same row also becomes calcified, and thus we have transverse bars of calcified substance stretching across from one calcareous column to another. Thus we have longitudinal groups of the cartilage which are formed of calcified cells enclosed in oblong cavities, the walls of matrix. These cavities are called the primary areola (Sharpey).

At the same time that this process is going on in the centre of the cartilage of which the foetal bone consists, certain changes are taking place on its surface. This is covered by a very vascular membrane, the periosteum, on the inner surface of which—that is to say, on the surface in contact with the cartilage—are a number of cells called osteoblasts. By the agency of these cells a thin layer of bony tissue is being formed between the periosteum and the cartilage, by the intramembranous mode of ossification presently to be described. We have then, in this first stage of ossification, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, enclosed by calcified matrix and containing the cartilage-cells enlarged and arranged in groups, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the periosteum (Fig. 32, †). The processes consist of blood-vessels and cells (osteoblasts). They excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (Fig. 32). Wherever these processes come in contact with the calcified walls of the
primary areolae they absorb it, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the secondary areolae (Sharpey).
wall of the space (Fig. 34). This layer of osteoblasts forms a bony stratum, and thus the wall of the space becomes gradually covered with a layer of true osseous substance. On this a second layer of osteoblasts arrange themselves, and in their turn form an osseous layer. By the repetition of this process the original cavity becomes very much reduced in size, and at last only remains as a small circular hole in the centre, containing the remains of the embryonic marrow—that is, a blood-vessel and a few osteoblasts. This small cavity constitutes the Haversian canal of the perfectly ossified bone. The successive layers of osseous matter which have been laid down and which encircle this central canal, constitute the lamellae of which, as we have seen, each Haversian system is made up. As the successive layers of osteoblasts form osseous tissue, certain of the osteoblastic cells remain included between the various bony layers. These continue persistent, and remain as the corpuscles of the future bone, the spaces enclosing them forming the lacunae (Fig. 34). The mode of the formation of the canaliculi is not known.

Such are the changes which may be observed at one particular point, the centre of ossification. While they have been going on here a similar process has been proceeding in the same manner toward the end of the shaft, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone in the centre of the shaft to the hyaline cartilage at the extremities. The bone thus formed differs from the bone of the adult in being more spongy and less regularly lamellated.

Thus far, then, we have followed the steps of a process by which a solid bony mass is produced, having vessels running into it from the periosteum, Haversian
canals in which those vessels run, medullary spaces filled with foetal marrow, lacunae with their contained bone-cells, and canaliculi growing out of these lacunæ.

This process of ossification, however, is not the origin of the whole of the skeleton, for even in those bones in which the ossification proceeds in a great measure from a single centre, situated in the cartilaginous shaft of a long bone, a considerable part of the original bone is formed by intramembranous ossification beneath the perichondrium or periosteum; so that the girth of the bone is increased by bony deposit from the deeper layer of this membrane. The shaft of the bone is at first solid, but a tube is hollowed out in it by absorption around the vessels passing into it, which becomes the medullary canal. This absorption is supposed to be brought about by large "giant-cells," which have long been recognized as a constituent of foetal marrow, and which are believed by Kölliker to have the power of absorbing or dissolving bone, and he has therefore named them "osteoclasts" (Fig. 33, f). They vary in shape and size, and are known by containing a large number of clear nuclei, sometimes as many as twenty. The occurrence of similar cells in some tumors of bones has led to such tumors being denominated "myeloid."

As more and more bone is removed by this process of absorption from the interior of the bone to form the medullary canal, so more and more bone is deposited on the exterior from the periosteum, until at length the bone has attained the shape and size which it is destined to retain during adult life. As the ossification of the cartilaginous shaft extends toward the articular ends it carries with it, as it were, a layer of cartilage, or the cartilage grows as it ossifies, and thus the bone is increased in length. During this period of growth the articular end, or epiphysis, remains for some time entirely cartilaginous; then a bony centre appears in it, and it commences the same process of intracartilaginous ossification; but this process never extends to any great distance. The epiphyses remain separated from the shaft by a narrow cartilaginous layer for a definite time. This layer ultimately ossifies, the distinction between shaft and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to the processes of bone which are separately ossified, such as the trochanters of the femur. The bones, having been formed, continue to grow until the body has acquired its full stature. They increase in length by ossification continuing to extend in the epiphyseal cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deeper layer of the periosteum, on their external surface, and at the same time an absorption takes place from within, by which the medullary cavity is increased.

The medullary spaces which characterize the cancellous tissue are produced by the absorption of the original foetal bone in the same way as the original medullary canal is formed. The distinction between the cancellous and compact tissue appears to depend essentially upon the extent to which this process of absorption has been carried; and we may perhaps remind the reader that in morbid states of the bone inflammatory absorption produces exactly the same change, and converts portions of bone naturally compact into cancellous tissue.

Intramembranous Ossification.—The intramembranous ossification is that by which the bones of the vertex of the skull are entirely formed. In the bones which are so developed no cartilaginous mould precedes the appearance of the bone-tissue. In the membrane which occupies the place of the future bone, a little network of bony spicule is first noticed, radiating from the point of ossification. When these rays of growing bone are examined by the microscope, they are found to consist of a network of fine clear fibres and granular cells with a ground-substance between. The fibres are termed osteogenic fibres, and soon become dark and granular from calcification, and as they calcify they are found to enclose the granular cells or "osteoblasts" (Fig. 36). The calcification not only involves the osteogenic fibres, but also the ground-substance of the tissue in which they
are contained. The cells at first lie upon the osteogenic fibres, so that they can be removed by brushing the specimen with a hair-pencil, in order to render the fibres clear; but they gradually become involved in the ossifying matrix, and form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacune. As the tissue increases in thickness, vessels shoot into it, grooving for themselves spaces or channels, which become the Haversian canals. Thus, the intramembranous and intraartilaginous processes of ossification are similar in their more essential features.

The number of ossific centres is different in different bones. In most of the short bones ossification commences by a single point in the centre, and proceeds toward the circumference. In the long bones there is a central point of ossification for the shaft or diaphysis; and one or more for each extremity, the epiphysis. That for the shaft is the first to appear. The union of the epiphyses with the shaft takes place in the reverse order to that in which their ossification began, and appears to be regulated by the direction of the nutrient artery of the bone. Thus, the nutrient arteries of the bones of the arm and fore-arm are directed toward the elbow, and the epiphyses of the bones forming this joint become united to the shaft before those at the opposite extremity. In the lower limb, on the other hand, the nutrient arteries pass in a direction from the knee; that is, upward in the femur, downward in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur, and the lower epiphysis of the tibia and fibula, become first united to the shaft.

Where there is only one epiphysis, the medullary artery is directed toward that end of the bone where there is no additional centre, as toward the acromial end of the clavicle, toward the distal end of the metacarpal bone of the thumb and great toe, and toward the proximal end of the other metacarpal and metatarsal bones.

Besides these epiphyses for the articular ends, there are others for projecting parts or processes, which are formed separately from the bulk of the bone. For an account of these the reader must be referred to the description of the individual bones in the sequel.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medico-legal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that, on the application of severe force to a joint, the epiphysis becomes separated from the shaft, and such injuries may be mistaken for fracture or dislocation.

**MUSCULAR TISSUE.**

The muscles are formed of bundles of reddish fibres, endowed with the property of contractility. Two kinds of muscular tissue are found in the animal body—viz. that of voluntary or animal life, and that of involuntary or organic life. The muscles of animal life (striped muscles) are capable of being put in action and controlled by the will. They are composed of bundles of fibres enclosed in a
delicate web called the “perimysium,” in contradistinction to the sheath of areolar tissue which invests the entire muscle, the “epimysium.” The bundles are termed “fasciculi;” they are prismatic in shape, of different sizes in different muscles, and for the most part placed parallel to one another, though they have a tendency to converge toward their tendinous attachments. Each fasciculus is made up of a bundle of fibres, which also run parallel with each other, and which are separated from one another by a delicate connective tissue derived from the perimysium, and termed endomysium (Fig. 37).

A muscular fibre may be said to consist of a soft contractile substance enclosed in a tubular sheath, named by Bowman the sarcolemma. The fibres are cylindrical or prismatic in shape, and are of no great length, not extending, it is said, further than an inch and a half. They end either by blending with the tendon or aponeurosis, or else by becoming drawn out into a tapering extremity which is connected to the neighboring fibre by means of the sarcolemma. Their breadth varies in man from \( \frac{1}{200} \) to \( \frac{1}{60} \) of an inch, the average of the majority being about \( \frac{1}{100} \).

As a rule, the fibres do not divide or anastomose; but occasionally, especially in the tongue and facial muscles, the fibres may be seen to divide into several branches. The precise mode in which the muscular fibre joins the tendon has been variously described by different observers. It may, perhaps, be sufficient to say that the sarcolemma, or membranous investment of the muscular fibre, appears to become blended with the tissue of the tendon, and prolonged more or less into the tendon, so that the latter forms a kind of sheath around the fibre for a longer or shorter distance. When muscular fibres are attached to the skin or mucous membranes, their sarcolemma probably becomes continuous with the fibres of the areolar tissue.

The sarcolemma, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it will sometimes remain entire when the included substance is ruptured (see Fig. 38). On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in the lower animals, elongated nuclei are seen (Fig. 55), and in connection with these a row of granules, apparently fatty, is sometimes observed.

Upon examination of a muscular fibre by transmitted light under a sufficiently high power, it is found to be apparently marked by alternate light and dark bands or striae, which pass transversely, or somewhat obliquely, round the fibre (Fig. 38). The dark and light bands are of nearly equal breadth, and alternate with great regularity. Other striae pass longitudinally over the fibres, though they are less distinct than the former. This longitudinal striation gives the fibre the appearance of being made up of a bundle of fibrillæ. The muscular fibre can be broken up either in a longitudinal or transverse direction (Fig. 39). If hardened in alcohol, it can be broken up longitudinally, and forms the so-called fibrillæ of which some suppose the fibre to be made up. Each fibril is marked by transverse striae, and appears to consist of a single row of minute quadrangular particles, named “sarcous elements” by Bowman. A still further division, however, is capable of being made, and each of these fibrillæ may be divided into minute threads (Fig. 40, b, d), consisting of an alternate dark and light spot. After exposure to the action of dilute hydrochloric acid, the muscular fibre can be broken transversely (Fig. 39, b). It then forms disks or plates, consisting of the same quadrangular particles, attached by their lateral surfaces.

Upon closer examination with a very high power the appearances become more complicated and are susceptible of various interpretations. The transverse striation, which in Figs. 38 and 39 appears as a mere alternation of dark and light
bands, is resolved into the appearance shown in Fig. 40, which shows a series of broad dark bands, separated by a light band, which is itself divided into two by a dark streak. This streak is termed Krause's membrane; it is continuous at each end with the sarcolemma investing the muscular fibre. Thus it may be said that the fibre is divided into a number of transverse compartments by this membrane, each compartment containing in the centre a dark plate with a bright border above and below; that is to say, between the dark central part and the membrane of Krause. A muscular fibre presents, then, the appearance of the following layers in regular alternation: a dark layer, the transverse disk; a bright transparent layer, the lateral disk; a dark line, the intermediate disk or membrane of Krause; then another lateral disk, a transverse disk, and so on (Figs. 40 and 41). This appearance, following the observations of Rollett, is due to the mode of for-

![Fig. 38.—Two human muscular fibres. Magnified 350 times. In the one, the bundle of fibrillae (b) is torn, and the sarcolemma (a) is seen as an empty tube.](image)

mation of a muscular fibre, which is made up of two principal parts: 1, fibrille; and 2, a hyaline or faintly granular substance, resembling protoplasm, and called sarcoplasm. The fibrille are arranged in bundles called muscular columns or sarcostyles, and these again in larger groups, which, collected together, form the fibre. The fibrillae are surrounded by the sarcoplasm, which surrounds also the columns and groups of columns, being in these latter situations greater in amount than between the fibrillae. So that on transverse section a muscular fibre is seen to be divided into a number of areas, called the areas of Cohnheim, more or less polyhedral in shape, and consisting of the columns of fibrille surrounded by transparent sheaths of sarcoplasm. And these areas are collected into larger or smaller groups, which in the same manner are surrounded by transparent sarcoplasm. Each area of Cohnheim presents a granular appearance due to the cross-section of its constituent fibrille, surrounded by a small amount of the hyaline sarcoplasm. The fibrillae extend throughout the whole length of, and are parallel to, the long axis of the muscular fibre. They present the following appearances in regular alternation: (1) a dim prismatic or rod-shaped element, the sarcous element of Bowman; (2) a thin bridge, which joins the sarcous element to (3) a dark granule. Then again...
another thin bridge joining the same granule to the next sarcolemma, and so on. When these fibrillae are collected together into columns, and the columns into muscular fibres, the appearance mentioned above is produced. The sarcolemmal elements, when arranged side by side and almost touching each other, with very little sarcoplasm between them, represent the transverse disk. The bridges, being much thinner than the sarcolemma or the dark granules, have between each other a much larger amount of sarcoplasm, and this gives to this part the transparent appearance of the lateral disk. And, lastly, the granules joined edge to edge in a row present the appearance of a membrane, which represents the intermediate disk.

On the muscular fibre, immediately beneath the sarcolemma, the sarcoplasm becomes here and there collected into small, plate-like masses. They contain oval nuclei, and are termed "muscle-corpuscles." Finally, in the centre of each sarcolemma a transparent lighter band can sometimes be discerned; this is known as the median disk of Hensen, and is due to the substance of the sarcolemmal elements being here thinner.

This form of muscular fibre composes the whole of the voluntary muscles, all the muscles of the ear, those of the larynx, pharynx, tongue, the upper half of the esophagus, the heart, and the walls of the large veins at the point where they open into it. The fibres of the heart, however, differ very remarkably from those of other striped muscles. They are smaller by one-third, and their transverse striae are by no means so distinct. The fibres are made up of distinct quadrangular cells joined end to end (Fig. 42). Each cell contains a clear oval nucleus, situated near the centre of the cell. The extremities of the cells have a tendency to branch or divide, the subdivisions uniting with offsets from other cells, and thus producing an anastomosis of the fibres (Fig. 42). The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

The capillaries of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. The larger vascular channels, arteries and veins, are

Membrane of Krause; owing to contraction during hardening, the sarcolemma shows regular bulgings. At the side of Krause's membrane is the transparent lateral disk. Several nuclei of muscle-corpuscles are shown, and in them a minute network.
found only in the perimysium, between the muscular fasciculi. The smaller vessels present peculiar saccular dilatations, which are supposed to act as receptacles for the blood during the contraction of the muscular fibres, when it is pressed out from some of the capillaries.

Nerves are profusely distributed to striped muscle. The mode of their termination will be described on a subsequent page.

The existence of lymphatic vessels in striped muscle has not been ascertained, though they have been found in tendons and in the sheath of the muscle.

The unstriped muscle, or muscle of organic life, is found in the walls of the hollow viscera—viz. the lower half of the oesophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi, and the alveoli and infundibula of the lungs; in the gall-bladder and ductus communis choledochus; in the large ducts of the salivary and pancreatic glands; in the pelvis and calices of the kidney, the ureter, bladder, and urethra; in the female sexual organs—viz. the ovary, the Fallopian tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the erectile tissue of the clitoris; in the male sexual organs—viz. the dartos scroti, the vas deferens and epididymis, the vesiculae seminales, the prostate gland, and the corpora cavernosa and corpus spongiosum; in the ducts of certain glands, as in Wharton’s duct; in the capsule and trabecule of the spleen; in the mucous membranes, forming the muscularis mucosae; in the skin, forming the arrectores pilorum, and also in the sweat-glands; in the arteries, veins, and lymphatics; in the iris and the ciliary muscle.

Plain or unstriped muscular fibre is made up of spindle-shaped cells, called contractile fibre-cells, collected into bundles and held together by a cement-substance, in which are contained some connective-tissue corpuscles (Fig. 43). These bundles are further aggregated into larger bundles or flattened bands, and bound together by ordinary connective tissue.

The contractile fibre-cells (Fig. 44) are elongated, spindle-shaped, nucleated cells of various lengths, averaging from \( \frac{1}{60} \) to \( \frac{1}{30} \) of an inch in length, and \( \frac{1}{38} \) to \( \frac{1}{32} \) of an inch in breadth. On transverse section they are more or less polygonal in shape, from mutual pressure. They present a faintly longitudinally striated appearance, and consist of an elastic cell-wall containing a central bundle of fibrillae, representing the contractile substance, and an oval or rod-like nucleus, which includes, within a membrane, a fine network communicating at the poles of the nucleus with the contractile fibres (Klein). The adhesive interstitial substance, which connects the fibre-cells together, represents the endomysium, or delicate connective tissue which binds the fibres of striped muscular tissue into fasciculi; while the tissue connecting the individual bundles together represents the perimysium. The unstriped muscle, as a rule, is not under the control of the will, nor is the contraction rapid and involving the whole muscle, as is the case with the muscles of animal life. The membranes which are composed of the unstriped muscle slowly contract in a part of their extent, generally under the influence of a mechanical stimulus, as that of distension or of cold; and then the contracted part slowly relaxes while another portion of the membrane takes up the contraction. This peculiarity of action is most strongly marked in the intestines, constituting their vermicular motion.

Chemical Composition of Muscle.—In chemical composition the muscular fibres of both forms consist mainly of a proteid substance—myosin—which is classed as one of the globulins. It is readily converted by the action of dilute acids
into synthonin or acid-albumen, and by the action of dilute alkalies into alkaline albumen. Muscle, which is neutral or slightly alkaline in reaction when at rest, is rendered acid by contraction, from the development probably of sarcolaetic acid. After death muscle also exhibits an acid reaction, but this appears to be due to post-mortem change.

NERVOUS TISSUE.

The nervous tissues of the body are comprised in two great systems—the cerebro-spinal and the sympathetic; and each of these systems consist of a central organ, or series of central organs, and of nerves.

The cerebro-spinal system comprises the brain (including the medulla oblongata), the spinal cord, the cranial nerves, the spinal nerves, and the ganglia connected with both these classes of nerves. The sympathetic system consists of a double chain of ganglia, with the nerves which go to and come from them. It is not directly connected with the brain or spinal cord, though it is so indirectly by means of its numerous communications with the cranial and spinal nerves.

Both these nervous systems are composed of an aggregation of tissue-elements termed neurons, each of which consists of a nucleated cell whose protoplasm is prolonged into a varying number of processes, one of which is usually of considerable length and forms the essential part of a nerve-fibre. The cell-bodies have a tendency to be associated together in more or less definite masses, such as the spinal and sympathetic ganglia, the central portion of the spinal cord, the floor of the medulla oblongata, the cortex of the cerebellum and of the cerebral hemispheres, and the various ganglia distributed through the different parts of the brain. These masses present macroscopically a grayish appearance, which contrasts strongly with the pure white color usually shown by the nerve-fibres, so that it is customary to speak of the nervous system as composed of two substances, the gray matter and the white or fibrous matter. The nerve-fibres of the sympathetic system, however, usually lack the constituent which gives the ordinary fibres their white appearance, and they consequently have a grayish color.

The gray substance is distinguished by its dark reddish-gray color and soft consistence. It is found in the brain, spinal cord, and various ganglia, intermingled with the fibrous nervous substance, and also in some of the nerves of special sense, and in gangliform enlargements which are found here and there in the course of certain cerebro-spinal nerves. It is composed, as its name implies,
of cells, commonly called **nerve-cells** or **ganglion-corpuscles**, containing nuclei and nucleoli. The cells together with the blood-vessels in the gray nerve-substance, and the nerve-fibres and vessels in the white nerve-substance, are imbedded in a peculiar ground-substance, named by Virchow **neuroglia**, and consisting of large branched cells (Fig. 46, C), the branches passing in every direction among the nerve-tissue, thus holding it and binding it together. It is developed from the epiblast, and contains neither the characteristic fibres nor cells of connective tissue, and therefore cannot be regarded as belonging to the true connective tissues. Each nerve-cell consists of a finely granular protoplasmic material, of a reddish or yellowish-brown color, which occasionally presents patches of a deeper tint, caused by the aggregation of pigment-granules (Fig. 45). No distinct limiting membrane or cell-wall has been ascertained to exist. The nucleus is, as a rule, a large, well-defined, round, vesicular body, often presenting an intranuclear network, and containing a nucleolus which is peculiarly clear and brilliant. The nerve-cells vary in shape and size; some are small, spherical or ovoid, with generally an even outline, such as those found in the spinal ganglia; others, again, are caudate or stellate in shape, and are characterized by their large size and by their having one or more tail-like processes issuing from them, which occasionally divide and subdivide into numerous branches (Fig. 46, A). These are found in greatest number in the gray matter of the spinal cord. Still others are flask-shaped, as in the cortex of the cerebellum; or conical, as in the cerebral convolutions. For the most part nerve-cells have one or more processes, and they are distinguished by the number of these processes, as unipolar, bipolar, or multipolar cells. These processes are very delicate and are direct continuations of the protoplasm of the nerve-cell. The majority of the processes of a multipolar cell are exceedingly fine, and branch dendritically, spreading out among the adjacent nervous elements; these processes are termed the **protoplasmic processes** or **dendrites**. One of the processes, however, does not thus branch, but gives off from time to time lateral branches termed **collaterals**, and eventually form the axis-cylinder of a nerve-fibre; this is the **axis-cylinder process**.

The **white** or **fibrous** nerve-substance or **nerve-fibre** is found universally in the
nervous cords, and also constitutes a great part of the brain and spinal cord. The fibres of which it consists are of two kinds, the medullated or white fibres, and the non-medullated or grey fibres.

The medullated fibres form the white part of the brain and spinal cord, and also the greater part of the cerebro-spinal nerves, and give to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body they present, when examined by transmitted light, a double outline or contour, as if consisting of two parts. The central portion is named the axis-cylinder of Purkinje; around this is a sort of sheath of fatty material, named the white substance of Schwann, which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the neurilemma, primitive sheath, or nucleated sheath of Schwann (Fig. 47).

The axis-cylinder is the essential part of the nerve-fibre, and is always present; the other parts, the medullary sheath and the neurilemma, being occasionally absent, especially at the origin and termination of the nerve-fibre. It undergoes no interruption from its origin in the nerve-centre to its peripheral termination, and must be regarded as a direct prolongation of a nerve-cell. It constitutes about one-half or one-third of the nerve-fibre, the white substance being greater in proportion in the nerves than in the central organs. It is perfectly transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. When examined under a high power it presents the appearance of longitudinal striation, as if composed of very fine, homogeneous fibrillae, held together in a faintly granular interstitial material. Occasionally at its termination the axis-cylinder of a fibre may be seen to break up into exceedingly fine fibrillae, confirming the view of its fibrillar structure. These fibrillae have been termed the primitive fibrillae of Schultz. The axis-cylinder is said to be enveloped in a very delicate, hyaline sheath, which separates it from the white matter of Schwann. The medullary sheath or white matter of Schwann is regarded as being a fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis-cylinder. The white matter varies in thickness to a very considerable extent, in some forming a layer of extreme thinness, so as to be scarcely distinguishable, in others forming about one-half the nerve-tube. The size of the nerve-fibres, which varies from 1/150 to 2/000 of an inch, depends mainly upon the amount of the white substance, though the axis-cylinder also varies in size within certain limits. The white matter of Schwann does not always form a continuous sheath to the axis-cylinder, but undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points. These were first described by Ranvier, and are known as the nodes of Ranvier (Fig. 48). The portion of nerve-fibre between two nodes is called an internodal segment. The neurilemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. Each

1 In older histological works the term "neurilemma" is used to designate the fibrous envelope of the whole nerve, now called "perineurium."
internodal segment contains an oval nucleus imbedded in the medullary sheath, and occasionally more than one nucleus may be seen in the same internode. Medullated nerve-fibres frequently present a beaded or varicose appearance: this is due to manipulation and pressure causing the oily matter to collect into drops, and in consequence of the extreme delicacy of the primitive sheath even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane. This is, of course, promoted by the action of ether (Fig. 49).

The neurilemma or primitive sheath (sometimes called the tubular membrane or sheath of Schwann) presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier; one nucleus generally lying in the centre of each node, though in some few instances two nuclei may be found in the same node. The sheath of Schwann, it is to be noted, does not occur in the medullated fibres contained within the spinal cord and brain.

**Non-medullated Fibres.**—Most of the nerves of the sympathetic system, and some of the cerebro-spinal (see especially the description of the olfactory nerve), consist of another variety of nervous fibres, which are called the gray or gelatinous nerve-fibres—fibres of Remak (Fig. 50). These consist of a bundle of finely striated fibrille enclosed in a sheath. Nuclei may be detected at intervals in each fibre, situated between the axis-cylinder and the neurilemma. In external appearance the gelatinous nerves are semi-transparent and gray or yellowish-gray. The individual fibres vary in size, generally averaging about half the size of the medullated fibres; but, on the one hand, the primitive fibrille formed by the breaking up of the cerebro-spinal fibres, as above mentioned, are of hardly appreciable thickness; while, on the other hand, some of the gelatinous fibres (especially those on the olfactory bulb) are said to be three or four times as thick as those of the cerebro-spinal nerves.

**Chemical Composition.**—The difference in the chemical composition of the white and gray matter is indicated by the following analyses by Petrowsky of the brain of the ox:

The proteids in the above analysis practically represent the protoplasm, which
naturally is much greater in the gray than in the white matter. On the other hand, the cholesterol, fat, and cerebrin (the latter ill-defined nitrogenous compounds belonging to the group of glucosides) are probably important constituents of the medullary sheath. Another substance also occurring in the medullary sheath, though not determined separately in the above analysis, is neurokeratin, which forms a fibrous network throughout the sheath, and resembles keratin in its marked resistance to reagents. It probably makes up the greater part of the unidentified organic matter of the white substance in the above analysis, while in the gray substance the unidentified matter is probably largely composed of protagon, a phosphorized compound closely resembling lecithin, but differing from it by its insolubility in ether.

The nervous structures are divided, as before mentioned, into two great systems—viz. the cerebro-spinal, comprising the brain and spinal cord, the nerves connected with these structures, and the ganglia situated on them; and the sympathetic, consisting of a double chain of ganglia and the nerves connected with them. All these structures require separate consideration.

The brain or encephalon is that part of the cerebro-spinal system which is contained in the cavity of the skull. It is divided into several parts, for a description of which reference must be made to the account of the structure of the brain in a subsequent portion of this work. In these parts the gray matter is found partly on the surface of the brain, forming the cortex of the cerebrum and of the cerebellum. Again, gray matter is found in the interior of the brain, collected into large and distinct masses or ganglionic bodies, such as the corpus striatum, optic thalamus, corpora quadrigemina, the olivary bodies, and the corpora dentata of the cerebellum. Finally, gray matter is found intermingled intimately with the white, but without definite arrangement, as in the gray matter in the pons Varolii and the floor of the fourth ventricle.

The white matter of the brain is divisible into three distinct classes of fibres. These are, in the first place, projection fibres, such as the fibres which connect the brain with the spinal cord; that is to say, those which are usually traced upward from the columns of the spinal cord, through the medulla oblongata into the encephalon, chiefly by means of the anterior pyramids, passing through the pons Varolii and crura cerebri to the internal capsules of the corpora striata, and thence to the cerebral cortex, and by means of the restiform bodies into the cerebellum. The second class of white fibres in the brain are commissural, connecting opposite sides of the brain, as, for instance, the fibres of the corpus callosum and the anterior commissure of the thalamencephalon. And the third class are the association fibres which connect different regions of the same side of any of the portions of the brain. The fibres of this last class are more especially developed in the cerebral hemispheres, where they connect different areas of the cortex, as, for example, the cortical centre for sight in the occipital lobe with the motor centre for speech in the frontal lobe.

The manner in which the gray and white matter are intermingled in the brain and spinal cord is very intricate, and can only be fully understood by a careful study of the details of its descriptive anatomy in the sequel. The further consideration of this subject will therefore be deferred until after the description of the various divisions of which the cerebro-spinal system is made up.

The nerves are round or flattened cords, formed of the nerve-fibres already described. They are connected at one end with the cerebro-spinal centre or with the ganglia, and are distributed at the other end to the various textures of the body; they are subdivided into two great classes—the cerebro-spinal, which proceed from the cerebro-spinal axis, and the sympathetic or ganglionic nerves, which proceed from the ganglia of the sympathetic. The cerebro-spinal nerves consist of numerous nerve-fibres collected together and enclosed in a membranous sheath (Fig. 51). A small bundle of primitive fibres, enclosed in a tubular sheath, is called a funiculus; if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or
fasciculi, which are bound together in a common membranous investment, and constitute the nerve.

In structure the common membranous investment, or sheath of the whole nerve, which is called the epineurium, as well as the septa given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the fasciculi, called the perineurium, consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it consists of connective tissue, which has a distinctly lamellar arrangement, consisting of several lamelle, separated from each other by spaces containing lymph. The nerve-fibres are held together and supported within the fasciculus by delicate connective tissue, called the endoneurium. It is continuous with septa which pass inward from the innermost layer of the perineurium, and consists of a ground-substance in which are imbedded fine bundles of fibrous connective tissue which run for the most part longitudinally. It serves to support the capillary vessels, which are arranged so as to form a network with the elongated meshes. The cerebro-spinal nerves consist almost exclusively of the medullated nerve-fibres, the non-medullated existing in very small proportions.

The blood-vessels supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres accompany these capillary vessels, vaso-motor fibres, and break up into elementary fibrils, which form a network around the vessel. Horsley has also recently demonstrated certain medullated fibres as running in the epineurium and terminating in tactile corpuscles or end-bulbs of Krause, or in small, but perfect, Pacinian corpuscles. These nerve-fibres are termed nervi nervorum, and have been considered to have an important bearing upon certain neuralgic pains.

The nerve-fibres, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component fasciculi, it may be seen that they do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other fasciculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other fasciculi. It must be remembered, however, that in these communications the nerve-fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve-fibres, and again pass on, to become blended with the nerve-fibres in some adjoining fasciculus.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighboring nerve. In the subdivision of a nerve the filaments of which it is composed are continued from the trunk into the branches,
and at their junction with the branches of neighboring nerves the filaments pass to become intermixed with those of the other nerves in their further progress; in no instance, however, have the separate nerve-fibres been shown to inosculate.

The communications which take place between two or more nerves form what is called a plexus. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nervous trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the individual filaments remain separate and distinct, and do not inosculate with one another.

It is probable that through this interchange of fibres the different branches passing off from a plexus have a more extensive connection with the spinal cord than if they each had proceeded to be distributed without such connection with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The sympathetic nerves are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of non-medullated fibres, collected into funiculi, and enclosed in a sheath of connective tissue. There is, however, in these nerves a certain admixture of medullated fibres, and the amount varies in different nerves. Those branches of the sympathetic which present a well-marked gray color are composed more especially of non-medullated nerve-fibres, intermixed with a few medullated fibres; whilst those of a white color contain more of the latter fibres and a few of the former. Occasionally, the gray and white cords run together in a single nerve, without any intermixture, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia. These medullated fibres are derived from the central nervous system through the rami communicantes, which pass from the cerebro-spinal nerves to the various sympathetic ganglia.

The nerve-fibres, both of the cerebro-spinal and sympathetic system, convey impressions of a twofold kind. The sensory nerves, called also centripetal or afferent nerves, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The motor nerves, called also centrifugal or efferent nerves, transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origin and Termination of Nerves.—By the expression "the termination of nerve-fibres" is signified their connection with the nerve-centres, and with the parts they supply. The former are sometimes called their origin, or central termination; the latter their peripheral termination. The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve-centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor and the posterior sensory. The point where the nerve root or roots emerge from the nervous centre is named the superficial or apparent origin, but the fibres of which the nerve consists can be traced for a certain distance into the nervous centre to some portion of the gray substance, which constitutes the deep or real origin of the nerve.
In the case of motor or efferent nerve-fibres the deep origin is in cells contained within the spinal cord or brain, the axis-cylinder processes of these cells being prolonged to form the fibres. In the case of the sensory nerves the origin is somewhat different, inasmuch as they arise from the cells of ganglia situated externally to the central nervous system. The sensory fibres of a spinal nerve arise, for instance, from the cells of the ganglion of the posterior root; these cells give off a process which branches in a T-shaped manner (Fig. 46, B), one of the limbs of the T extending peripherally, while the other passes inwards and penetrates the spinal cord. In connection with the sensory cranial nerves, origins are described imbedded within the substance of the brain; these are not, however, the proper origins, but are groups of cells around which the fibres, growing inwards form the ganglion-cells, situated just outside the brain, end, and from which new fibres arise, which pass upwards in the substance of the brain.

Peripheral Terminations of Nerves. — The manner in which nerve-fibres terminate peripherally are several, and may be conveniently studied in the sensory and motor nerves respectively. Sensory nerves would appear to terminate either in minute primitive fibrille or networks of these; or else in special terminal organs, which have been termed peripheral end-organs, and of which there are three principal varieties — viz. the end-bulbs of Krause, the tactile corpuscles of Wagner, and the Pacinian corpuscles.

Termination in Fibrille. When a medullated nerve-fibre approaches its termination, the white matter of Schwann suddenly disappears, leaving only the axis-cylinder surrounded by the neurilemma, and we have now a non-medullated fibre. This undergoes repeated division, and after a time loses its neurilemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrils. Finally, the axis-cylinder breaks up into its constituent primitive nerve-fibrille, which anastomose with one another, thus forming a network, and often present regular varicosities. This network passes between the elements of the tissue to which the nerves are distributed, which is always epithelial, and the nerve-fibrils end in the interstitial substance between the epithelial cells, or, as is believed by some, actually terminate within the cells as minute swellings close to the nucleus. In this way nerve-fibres have been found to terminate in the epithelium of the skin and mucous membranes, and in the anterior epithelium of the cornea.

The end-bulbs of Krause (Fig. 52) are minute oblong or cylindrical corpuscles, into the interior of which the axis-cylinder of the nerve-fibre passes, and terminates in a coiled, plexiform mass or in a bulbous extremity. The corpuscle consists of a simple nucleated capsule, containing a soft, homogeneous core, in which the termination of the axis-cylinder is contained. The white matter of Schwann ceases abruptly as the axis-cylinder enters the corpuscle, but the neurilemma is continued inward with the axis-cylinder, and forms an investment of the core, lining the interior of the capsule. The end-bulbs have been described as occurring in the conjunctiva (where, in man, they are spheroidal in shape), in the mucous membrane of the mouth, and in the cutis and mucous membrane of the penis, clitoris, and vagina, where they are termed genital corpuscles. The latter have a mulberry-like appearance, from being constricted by connective-tissue septa into from two to six knob-like masses. In the synovial membrane of certain joints (e.g. those of the fingers) rounded or oval end-bulbs have been found; these are designated articular end-bulbs.

The tactile corpuscles (Fig 53), described by Wagner and Meissner, are oval-shaped bodies, made up of connective tissue, and consisting of a capsule, and imperfect membranous septa, derived from it, which penetrate its interior. The axis-cylinders, entering the capsule, pursue a convoluted course, supported by the septa, and terminate in small globular or pyriform enlargements, near the inner surface of the capsule. These tactile corpuscles have been described as occurring in the papillae of the corium of the hand and foot, the front of the fore-arm, the
skin of the lips, and the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the nipple. They are not found in all the papillae;

but from their existence in those parts in which the skin is highly sensitive, it is probable that they are specially concerned in the sense of touch, though their absence from the papillae of other tactile parts shows that they are not essential to this sense.

The Pacinian corpuscles\(^1\) (Fig. 54) are found in the human subject chiefly on the nerves of the palm of the hand and sole of the foot and in the genital organs of both sexes, lying in the subcutaneous tissue; but they have also been described as connected with the nerves of the joints, and in some other situations, as the mesentery of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle, which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat), consists of a number of lamellae or capsules, arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective-tissue fibres, and is lined on its inner surface by a single layer of nucleated endothelial cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent material, in the middle of which is the single medullated fibre, which traverses the space to near its distal extremity. Here it terminates in a rounded knob or end, sometimes bifurcating previously, in which case each branch has a similar arrangement. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space. Other authors describe the artery as entering the corpuscle at the pole opposite to the nerve-fibre.

Herbst has described a somewhat similar "nerve-ending" to the Pacinian corpuscle, as being found in the mucous membrane of the tongue of the duck and in some other situations. It differs, however, from the Pacinian corpuscles, in being smaller, its capsules thinner and more closely approximated, and especially in the fact that the axis-cylinder in the central clear space is coated with a continuous row of nuclei. These bodies are known as the corpuscles of Herbst.

Tactile corpuscles have been described by Grandry as occurring in the papillae of the beak and tongue of birds, and by Merkel as occurring in the papillae and

\(^1\) Often called in German anatomical works "corpuscles of Vater."

epithelium of the skin of man and animals, especially in those parts of the skin devoid of hair. They consist of a capsule composed of a very delicate, nucleated membrane, and contain two or more granular, somewhat flattened cells, between which the medullated nerve-fibre, which enters the capsule by piercing its investing membrane, is supposed to terminate.

The nerves supplying tendons have peculiar nerve-endings, and are especially numerous near the point where the tendon becomes muscular. In this situation spindle-shaped bodies are found, and are known as the organs of Golgi. They are apparently composed of several tendinous bundles fused into one, into which one or more nerve-fibres pass, and, dividing, spread out between the tendon-bundles. Nerve-fibres occasionally terminate in tendons as end-bulbs or as small Pacinian corpuscles.

In the organs of special sense the nerves seem to terminate in cells, which are modified epithelial cells, and have received the name of sensory or nerve-epithelium cells. In reality, however, the nerve-fibre is in these cases a process of the epithelial cell, and if followed centrally will be found to end by branching around a ganglion-cell. From this an axis-cylinder continues the path along which the stimulus travels toward the brain. These nerve-epithelium cells are to be regarded as specially modified neurons.

Motor nerves are to be traced either into unstriped or striped muscular fibres. In the unstriped or involuntary muscles the nerves are derived from the sympathetic, and are composed mainly of the non-medullated fibres. Near their termination they divide into a number of branches, which communicate and form an intimate plexus.

At the junction of the branches groups of ganglion-cells are situated. From these plexuses minute branches are given off, which divide and break up into the ultimate fibrille of which the nerve is composed. These fibrille course between the involuntary muscle-cells, and, according to Elischer, terminate on the surface of the cell, opposite the nucleus, in a minute swelling. Arnold and Frankenhäuser believed that these ultimate fibrille penetrated the muscular cell and ended in the nucleus. More recent observation has, however, tended to disprove this.

In the striped or voluntary muscle, the nerves supplying the muscular fibres are derived from the cerebro-spinal nerves, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres, or bundles of fibres, which form plexuses, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre is long, more than one nerve-fibre enters it. Within the muscular fibre the nerve terminates in a special expansion, called by Kühne, who first accurately described them, motorial end-plates (Fig. 55). The nerve-fibre, on approaching the muscular fibre, suddenly loses its white matter of Schwann, which abruptly terminates; the neurilemma becomes continuous with the sarcolema of the muscle, and only the axis-cylinder enters the muscular fibre, where it immediately spreads out, ramifying like the roots of a tree, immediately beneath

---

1 They had, however, previously been noticed, though not accurately described, by Doyere, who named them "nerve-hillocks."
the sarcolemma, and is imbedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

The Ganglia may be regarded as separate and independent nervous centres, of smaller size and less complex structure than the brain, connected with each other, with the cerebro-spinal axis, and with the nerves in various situations. They are found on the posterior root of each of the spinal nerves; on the posterior or sensory root of the fifth cranial nerve; on the facial and auditory nerves; and on the glossopharyngeal and pneumogastric nerves. They are also found in a connected series along each side of the vertebral column, forming the trunk of the sympathetic; and on the branches of that nerve, generally in the plexuses or at the point of junction of two or more nerves with each other or with branches of the cerebro-spinal system. On section they are seen to consist of a reddish-gray substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. The ganglia are invested by a smooth and firm, closely-adhering, membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the peri-neurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the blood-vessels supplying its substance.

In structure all ganglia are essentially similar (Fig. 56), consisting of the same structural elements as the other nervous centres—viz. a collection of nerve-cells and nerve-fibres. The nerve- or ganglion-cells in the ganglia of the spinal nerves are pyriform in shape, the
smaller end being drawn out into a process which bifurcates at its extremity in a T-like manner, the two limbs of the T forming the axis-cylinder of the peripheral and central portions of a sensory nerve-fibre. In the sympathetic ganglia the cells are multipolar, and give off a single unbranched axis-cylinder. Cells of this type are found in the ciliary, sphenopalatine, submaxillary, and otic ganglia attached to certain of the cranial nerves, and these may in consequence be considered as the cranial portion of the sympathetic system. The ganglion-cells are usually enclosed in a transparent capsule with nuclei on its inner surface. The nerve-fibres on entering the ganglion lay aside their perineurium, which becomes continuous with the capsule. Some fibres run through the ganglion without being connected with the cells.

THE VASCULAR SYSTEM.

The Vascular System, exclusive of its central organ, the heart, is divided into four classes of vessels: the arteries, capillaries, veins, and lymphatics; the minute structure of which we will now proceed briefly to describe, referring the reader to the body of the work for all that is necessary in the details of their ordinary anatomy.

Structure of Arteries (Fig. 57).—The arteries are composed of three coats: internal or endothelial coat (tunica intima of Kölliker); middle muscular coat (tunica media); and external cellular coat (tunica adventitia).

The two inner coats together are very easily separated from the external, as by the ordinary operation of tying a ligature on an artery. If a fine string be tied forcibly upon an artery and then taken off, the external coat will be found undivided, but the internal coats are divided in the track of the ligature and can easily be further dissected from the outer coat. The inner coat can be separated from the middle by a little maceration, or it may be stripped off in small pieces; but, on account of its friability, it cannot be separated as a complete membrane. It is a fine, transparent, colorless structure which is highly elastic, and is commonly corrugated into longitudinal wrinkles. The inner coat consists of—

1. A layer of pavement-epithelium, the cells of which are polygonal, oval, or fusiform, and have very distinct round or oval nuclei. This endothelium, as it is now generally called, is brought into view most distinctly by staining with nitrate of silver.

2. A subepithelial layer, consisting of delicate connective tissue with branched cells lying in the interspaces of the tissue. 3. An elastic or fenestrated layer, which consists of an elastic membrane containing a network of elastic fibres, having principally a longitudinal direction and in which, under the microscope, small, elongated apertures or perforations may be seen, giving it a fenestrated appearance. It was therefore called by Henle the fenestrated membrane. This membrane forms the chief thickness of the inner coat, and can be separated into several layers, some of which present the appearance of a network of longitudinal elastic
fibres, and others present a more membranous character, marked by pale lines having a longitudinal direction. In arteries of less than a line in diameter the subepithelial layer consists of a single layer of stellate cells, and the connective tissue is only largely developed in the large-sized vessels. The fenestrated membrane in microscopic arteries is a very thin layer, but in the larger arteries, and especially in the aorta, it has a very considerable thickness.

The middle coat (tunica media) is distinguished from the inner by its color and by the transverse arrangement of its fibres, in contradistinction to the longitudinal direction of those of the inner coat. It consists of two varieties of structure, yellow elastic tissue and muscular tissue, which are present in varying quantities in different vessels, according to their size, the former tissue preponderating in the larger vessels and the latter in the smaller ones. In the largest arteries this coat is of great thickness, of a yellow color, and highly elastic; it diminishes in thickness and becomes redder in color as the arteries become smaller, and finally becomes very thin and disappears. In small arteries this coat is purely muscular, consisting of muscle fibre-cells (Fig. 44) united to form lamellae which vary in number according to the size of the artery; the very small arteries having only a single layer, and those not larger than one-tenth of a line in diameter three or four layers. In arteries of medium size (Fig. 58) this coat becomes thicker in proportion to the size of the vessel; its layers of muscular tissue are more numerous and intermixed with numerous fine elastic fibres which unite to form broad-meshed networks. In the larger vessels, as the femoral, superior mesenteric, coeliac axis, external iliac, brachial and popliteal arteries, the elastic fibres unite to form lamellae, which alternate with the layers of muscular fibre. In the largest arteries the muscular tissue is only slightly developed and forms about one-third or one-fourth of the whole substance of the middle coat; this is especially the case in the aorta and trunk of the pulmonary artery, in which the individual cells of the muscular layer are imperfectly formed, while in the carotid, axillary, iliac, and subclavian arteries the muscular layer of the middle coat is more developed. The elastic lamellae are well marked, may amount to fifty or sixty in number, and alternate regularly with the layers of muscular tissue. They are most distinct and arranged with greatest regularity in the abdominal aorta, innominate artery, and common carotid. In the larger arteries bundles of white connective-tissue fibres have also been found in small quantity in the middle coat.

The external coat (tunica adventitia) consists mainly of fine and closely felted bundles of white connective tissue, but also contains elastic fibres in all but the smallest arteries. The elastic tissue is much more abundant next the tunica media, and it is sometimes described as forming here, between the adventitia and media, a special layer, the tunica elastica externa of Henle. This layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin; but in small arteries it is as thick or thicker than the middle coat.
In the smaller arteries it consists of a single layer of white connective tissue and elastic fibres; while in the smallest arteries, just above the capillaries, the elastic fibres are wanting, and the connective tissue, of which the coat is composed, becomes more homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope which finally disappears.

Some arteries have extremely thin coats in proportion to their size; this is especially the case in those situated in the cavity of the cranium and spinal canal, the difference depending on the greater thinness of the external and middle coats.

The arteries, in their distribution throughout the body, are included in a thin fibro-areolar investment, which forms what is called their sheath. In the limbs this is usually formed by a prolongation of the deep fascia; in the upper part of the thigh it consists of a continuation downward of the transversalis and iliac fasciae of the abdomen; in the neck, of a prolongation of the deep cervical fascia. The included vessel is loosely connected with its sheath by a delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve. Some arteries, as those in the cranium, are not included in sheaths.

All the larger arteries are supplied with blood-vessels like the other organs of the body; they are called the vasa vasorum. These nutrient vessels arise from a branch of the artery or from a neighboring vessel, at some considerable distance from the point at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat, but do not, in man, penetrate the other coats; though in some of the larger mammals some few vessels have been traced into the middle coat. Minute veins serve to return the blood from these vessels; they empty themselves into the venules comites in connection with the artery. Lymphatic vessels and lymphatic spaces are also present in the outer coat.

Arteries are also supplied with nerves, which are derived chiefly from the sympathetic, but partly from the cerebro-spinal system. They form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller branches as single filaments or bundles of filaments, which twist around the vessel and unite with each other in a plexiform manner. The branches derived from these plexuses penetrate the external coat, and are principally distributed to the muscular tissue of the middle coat, and thus regulate, by causing the contraction and relaxation of this tissue, the amount of blood sent to any part.

The Capillaries.—The smaller arterial branches (excepting those of the cavernous structure of the sexual organs, of the spleen, and in the uterine placenta) terminate in a network of vessels which pervade nearly every tissue of the body. These vessels, from their minute size, are termed capillaries (capillitus, a hair). They are interposed between the smallest branches of the arteries and the commencing veins, constituting a network, the branches of which maintain the same diameter throughout; the meshes of the network being more uniform in shape and size than those formed by the anastomoses of the small arteries and veins.

The diameter of the capillaries varies in the different tissues of the body, their usual size being about \( \frac{1}{100} \) of an inch. The smallest are those of the brain and the mucous membranes of the intestines; and the largest those of the skin and the marrow of bone, where they are stated to be as large as \( \frac{1}{100} \) of an inch.

The form of the capillary net varies in the different tissues, the meshes being generally rounded or elongated. The rounded form of mesh is most common, and prevails where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis; here the meshes are more or less angular, sometimes nearly quadrangular or polygonal; more frequently irregular.

Elongated meshes are observed in the bundles of fibres composing muscles and nerves, the meshes being usually of a parallelogram form, the long axis of the mesh running parallel with the long axis of the nerve and fibre. Sometimes the capillaries have a looped arrangement; a single vessel projecting from the
common network and returning after forming one or more loops, as in the papillae of the tongue and skin. The number of the capillaries, and the size of the meshes, determine the degree of vascularity of a part. The closest network and the smallest interspaces are found in the lungs and in the choroid coat of the eye. In these situations the interspaces are smaller than the capillary vessels themselves. In the kidney, in the conjunctiva, and in the cutis the interspaces are from three to four times as large as the capillaries which form them; and in the brain from eight to ten times as large as the capillaries in their long diameter, and from four to six times as large in their transverse diameter. In the adventitia of arteries the width of the meshes is ten times that of the capillary vessels. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of blood; the network being very narrow in all growing parts, in the glands, and in the mucous membranes; wider in bones and ligaments, which are comparatively inactive; and nearly altogether absent in tendons, in which very little organic change occurs after their formation.

Structure.—The walls of the capillaries consist of a fine, transparent, endothelial layer, composed of cells joined edge to edge by an interstitial cement-substance, and continuous with the endothelial cells which line the arteries and veins. When stained with nitrate of silver the edges which bound the endothelial cells are brought into view (Fig. 59). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus which may be brought into view by carmine or haematoxylin. Between their edges, at various points of their meeting, roundish dark spots are sometimes seen, which have been described as stomata, though they are closed by intercellular substance. They have been believed to be the situation through which the white corpuscles of the blood, when migrating through the blood-vessels, emerge; but this view, though probable, is not universally accepted.

In many situations a delicate sheath or envelope of branched nucleated connec-
tive-tissue cells is found around the simple capillary tube, particularly in the larger ones, and in places such as the lymphatic glands where the capillaries are supported by a retiform connective tissue.

In the largest capillaries (which ought, perhaps, to be described rather as the smallest arteries) there is, outside the endothelial layer, a muscular layer, consisting of contractile fibre-cells, arranged transversely, as in the tunic media of the larger arteries (Fig. 60).

The veins, like the arteries, are composed of three coats—internal, middle, and external; and these coats are, with the necessary modifications, analogous to the coats of the arteries; the internal being the endothelial, the middle the muscular, and the external the connective or areolar. The main difference between the veins and the arteries is the comparative weakness of the middle coat of the former, and to this it is due that the veins do not stand open when divided, as the arteries do, and that they are passive rather than active organs of the circulation.

In the veins immediately above the capillaries the three coats are hardly to be distinguished. The endothelium is supported on an outer membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (adventitia), while the inner is composed of a network of longitudinal elastic fibres (media). In the veins next above these in size (one-fifth of a line, according to Kölliker) a muscular layer and a layer of circular fibres can be traced, forming the middle coat, while the elastic and connective elements of the outer coat become more distinctly perceptible. In the middle-sized veins the typical structure of these vessels becomes clear. The endothelium is of the same character as in the arteries, but its cells are more oval, less fusiform. It is supported by a connective-tissue layer, consisting of a delicate network of branched cells, and external to this is a layer of longitudinal elastic fibres, but seldom any appearance of a fenestrated membrane. This constitutes the internal coat. The middle coat is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a transverse layer of muscular fibres. The white fibrous element is in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The outer coat consists of areolar tissue, as in the arteries, with longitudinal elastic fibres. In the largest veins the outer coat is from two to five times thicker than the middle coat, and contains a large number of longitudinal muscular fibres. This is most distinct in the inferior vena cava, and at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the vena portae, in the splenic, superior mesenteric, external iliac, renal, andazygos veins. In the renal and portal veins it extends through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. All the large veins which open into the heart are covered for a short distance with a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting in the veins—(1) of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater of the brain and spinal cord; (3) in the veins of the retina; (4) in the veins of the cancellous tissue of bones; (5) in the venous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an internal endothelial lining supported on one or more layers of areolar tissue. The internal and external jugular veins and the subclavian vein are said to contain either no muscular fibres at all, or at all events only a slight amount in their middle coat.

Most veins are provided with valves, which serve to prevent the reflux of the blood. They are formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and are covered on both surfaces with endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein the cells are arranged transversely; whilst on the other surface, over which the current of blood flows, the cells are arranged vertically in the direction of the current. Their form is semilunar. They are
attached by their convex edge to the wall of the vein; the concave margin is free, directed in the course of the venous current, and lies in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is intercepted. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three and sometimes only one. The wall of the vein on the cardiac side of the point of attachment of each segment of the valve is expanded into a pouch or sinus, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially of the lower extremities, these vessels having to conduct the blood against the force of gravity. They are absent in the very small veins—i.e. those less than \( \frac{1}{2} \) of an inch in diameter; also in the vena cave, the hepatic veins, portal vein and its branches, the renal, uterine, and ovarian veins. A few valves are found in the spermatic veins, and one also at their point of junction with the renal vein and inferior vena cava in both sexes. The cerebral and spinal veins, the veins of the cancellated tissue of bone, the pulmonary veins, and the umbilical vein and its branches, are also destitute of valves. They are occasionally found, few in number, in the veins azygos and intercostal veins.

The veins are supplied with nutrient vessels, vasa vasorum, like the arteries. Nerves also are distributed to them in the same manner as to the arteries, but in much less abundance.

The lymphatic vessels, including in this term the lacteal vessels, which are identical in structure with them, are composed of three coats. The internal is an endothelial and elastic coat. It is thin, transparent, slightly elastic, and ruptures sooner than the other coats. It is composed of a layer of elongated epithelial cells with serrated margins, by which the adjacent cells are dovetailed into one another. These are supported on a single layer of longitudinal elastic fibres. The middle coat is composed of smooth muscular and fine elastic fibres, disposed in a transverse direction. The external, or fibro-areolar, coat consists of filaments of connective tissue, intermixed with smooth muscular fibres, longitudinally or obliquely disposed. It forms a protective covering to the other coats, and serves to connect the vessel with the neighboring structures. The above description applies only to the larger lymphatics; in the smaller vessels there is no muscular or elastic coat, and their structure consists only of a connective-tissue coat, lined by endothelium. The thoracic duct (Fig. 61) is a somewhat more complex structure than the other lymphatics; it presents a distinct subepithelial layer of branched corpuscles, similar to that found in the arteries, and in the middle coat is a layer of connective tissue with its fibres.
arranged longitudinally. The lymphatics are supplied by nutrient vessels, which are distributed to their outer and middle coats; but no nerves have at present been traced into them.

The lymphatics are very generally provided with valves, which assist materially in effecting the circulation of the fluid they contain. These valves are formed of a thin layer of fibrous tissue, lined on both surfaces by endothelium. Their form is semilunar; they are attached by their convex edge to the sides of the vessel, the concave edge being free and directed along the course of the contained current. Usually two such valves, of equal size, are found opposite one another; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. Thus, one valve may be of very rudimentary size and the other increased in proportion.

The valves in the lymphatic vessels are placed at much shorter intervals than in the veins. They are most numerous near the lymphatic glands, and they are found more frequently in the lymphatics of the neck and upper extremity than in the lower. The wall of the lymphatics immediately above the point of attachment of each segment of a valve is expanded into a pouch or sinus, which gives to these vessels, when distended, the knotted or beaded appearance which they present. Valves are wanting in the vessels composing the plexiform network in which the lymphatics usually originate on the surface of the body.

Origin of Lymphatics.—The finest visible lymphatic vessels (lymphatic capillaries) form a plexiform network in the tissues and organs, and they consist of a single layer of endothelial plates, with more or less sinusous margins. These vessels commence in an intercommunicating system of clefts or spaces in the connective tissue of the different organs, which have no complete endothelial lining. They have been named the rootlets of the lymphatics, and are identical with the spaces in which the connective-tissue corpuscles are contained. This then is properly regarded as one method of their commencement, when the lymphatic vessels are apparently continuous with spaces in the connective tissue, and Klein has described and figured a direct communication between these spaces and the lymphatic vessel.1 But the lymphatics have also other modes of origin, for the intestinal lacteals commence by closed extremities, though some observers believe that the closed extremity is continuous with a minute network contained in the substance of the villus, through which the lacteal is connected with the epithelial cells covering it. Again, it seems now to be conclusively proved that the serous membranes present stomata or openings between the epithelial cells (Fig. 62) by which there is an open communication with the lymphatic system, and through which the lymph is thought to be pumped by the ultimate dilatation and contraction of the serous surface, due to the movements of respiration and circulation,2 so that the serous and synovial sacs may be regarded, in a certain sense, as large lymph-cavities or sinuses. Von Recklinghausen was the first to observe the passage of milk and other colored fluids through these stomata on the peritoneal surface of the central tendon of the diaphragm. Again, in most glandular structures the lymphatic capillaries have a lacunar origin. Here they begin in irregular clefts or spaces in the tissue of the part; occupying the penetrating connective tissue and surrounding the lacunae or tubules of the gland, and in many places separating the capillary network from the alveolus or tubule, so that the interchange between the blood and the secreting cells of the part must be carried on through this lymph-space or lacuna. Closely allied to this is the mode of origin of lymphatics in perivascular and perineural spaces. Sometimes a minute artery may be seen to be ensheathed for a certain distance by a lymphatic capillary vessel, which is often many times wider than a blood-capillary. These are known as perivascular lymphatics.

1 Atlas of Histology, pl. viii. fig. xiv.
2 The resemblance between lymph and serum led Hewson long ago to regard the serous cavities as sacs into which the lymphatics open. Recent microscopic discoveries confirm this opinion in a very interesting manner.
Terminations of Lymphatics.—The lymphatics, including the lacteals, discharge their contents into the veins at two points; namely, at the angles of junction of the subclavian and internal jugular veins: on the left side by means of the thoracic duct, and on the right side by the right lymphatic duct. (See description of lymphatics on a subsequent page.)

Lymphatic glands (conglolate glands) are small oval or bean-shaped bodies, situated in the course of lymphatic and lacteal vessels, so that the lymph and chyle pass through them on their way to the blood. They generally present on one side a slight depression—the hilum—through which the blood-vessels enter and leave the interior. The efferent lymphatic vessel also emerges from the gland at this spot, while the afferent vessels enter the organ at different parts of the periphery. On section (Fig. 63), a lymphatic gland displays two different structures: an external, of lighter color—the cortical; and an internal, darker—the medullary. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent vessel is derived directly from the medullary structure, while the afferent vessels empty themselves into the cortical substance.

Lymphatic glands consist of (1) a fibrous envelope, or capsule, from which a framework of processes (trabeculae) proceed inward, dividing the gland into open spaces (alveoli) freely communicating with each other; (2) a quantity of adenoid tissue occupying these spaces without completely filling them; (3) a free supply of blood-vessels, which are supported on the trabeculae; and (4) the afferent and efferent vessels. Little is known of the nerves, though Kölliker describes some fine nervous filaments passing into the hilum.

The capsule is composed of a layer of connective tissue, and from its internal surface are given off a number of membranous septa or lamellae, consisting, in man, of connective tissue, with a small admixture of muscular fibre-cells; but in many of the lower animals composed almost entirely of involuntary muscular fibre. They pass inward, radiating toward the centre of the gland, for a certain distance; that is to say, for about one-third or one-fourth of the space between the circumference and the centre of the gland. They thus divide the outer part of its interior into a number of oval compartments or alveoli (Fig. 63). This is the cortical portion of the gland. After having penetrated into the gland for some distance, these septa break up into a number of smaller trabeculae, which form flattened bands or cords, interlacing with each other in all directions, forming in the central part of the organ a number of intercommunicating spaces, also called alveoli. This is the medullary portion of the gland, and the spaces or alveoli in it not only freely communicate with each other, but also with the alveoli of the cortical portion. In these alveoli or spaces (Fig. 64) is contained the proper gland-substance or lymphoid tissue. The gland-pulp does not, however, completely fill the alveolar spaces, but leaves, between its outer margin and the trabeculae forming the alveoli a channel or space of uniform width throughout. This is termed the lymph-path or lymph-sinus (Fig. 66). Running across it are a number of trabeculae of retiform connective tissue, the fibres of which are, for the most part, covered by ramified cells. This tissue appears to serve the purpose of maintaining the gland-pulp in the centre of the space in its proper position.
On account of the peculiar arrangement of the framework of the organ, the gland-pulp in the cortical portion is disposed in the form of nodules, and in the medullary part in the form of rounded cords. It consists of ordinary lymphoid tissue, being made up of a delicate reticulum of retiform tissue, which is continuous with that in the lymph-paths, but marked off from it by a closer reticulation; in its meshes are closely packed lymph-corpuscles, traversed by a dense plexus of capillary blood-vessels.

The **afferent vessels**, as above stated, enter at all parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule, open into the lymph-sinuses of the cortical part. In doing this they lose all their coats except their endothelial lining, which is continuous with a layer of similar cells lining the lymph-paths. In like manner the **efferent vessel** commences from the lymph-sinuses of the medullary portion. The stream of lymph carried to the gland by the afferent vessel thus passes through the plexus in the capsule to the lymph-paths of the cortical portion, where it is exposed to the action of the gland-pulp; flowing through these, it enters the paths or sinuses of the medullary portion, and finally emerges from the hilum by means of the efferent vessel. The stream of lymph in its passage through the lymph-sinuses is much retarded by the presence of the reticulum. Hence morphological elements, either normal or...
morbid, are easily arrested and deposited in the sinuses. This is a matter of considerable importance in connection with the subject of poisoned wounds and the absorption of the poison by the lymphatic system, since by this means septic organisms carried along the lymphatic vessels may be arrested in the lymph-sinuses of the gland tissue, and thus be prevented from entering the general circulation. The arteries of the gland enter at the hilum, and either pass at once to the gland-pulp, to break up into a capillary plexus, or else run along the trabeculae, partly to supply them and partly running across the lymph-paths to assist in forming the capillary plexus of the gland-pulp. This plexus traverses the lymphoid tissue, but does not pass into the lymph-sinuses. From it the veins commence, and emerge from the organ at the same place as that at which the artery enters.

THE SKIN AND ITS APPENDAGES.

The skin (Fig. 67) is the principal seat of the sense of touch, and may be regarded as a covering for the protection of the deeper tissues; it is also an important excretory and absorbing organ. It consists principally of a layer of vascular connective tissue, named the derma, corium, or cutis vera, and an external covering of epithelium, termed the epidermis or cuticle. On the surface of the former layer are the sensitive papillae; and within, or imbedded beneath it, are certain organs with special functions—namely, the sweat-glands, hair-follicles, and sebaceous glands.

The epidermis or cuticle (scarf-skin, Fig. 68) is an epithelial structure belonging to the class of stratified epithelium. It is accurately moulded on the papillary layer of the derma. It forms a defensive covering to the surface of the true skin, and limits the evaporation of watery vapor from its free surface. It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be partly due
to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layer of cells, called the horny layer

*(stratum corneum)*, may be separated by maceration from the deeper layers, which are called the *rete mucosum*, and which consist of several layers of differently shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, marking out the surface into a number of spaces of polygonal or lozenge-shaped form. Some of these furrows are large, as opposite the flexures of the joints, and correspond to the folds in the derma produced by their movements. In other situations, as upon the back of the hand, they are exceedingly fine, and intersect one another at various angles; upon the palmar surface of the hand and fingers and upon the sole of the foot these lines are very distinct and are disposed in curves. They depend upon the large size and peculiar arrangement of the papillae upon which the epidermis is placed. The deep surface of the epidermis is accurately moulded upon the papillary layer of the derma, each papilla being invested by its epidermic sheath; so that when this layer is removed by maceration, it presents on its under surface a number of pits or depressions corresponding to the elevations in the papille, as well as the ridges left in the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

In structure, the epidermis consists of several layers of epithelial cells agglutinated together and having a laminated arrangement. These several layers may be described as composed of four different strata from within outward: (1) The *rete Malpighii*, composed of several layers of epithelial cells, of which the deepest layer is elongated in figure and placed perpendicularly on the surface of the corium, their lower ends being denticulate, to fit into corresponding denticulations of the true skin; while the succeeding laminae consist of cells of a more rounded or polyhedral form, the contents of which are soft, opaque, granular, and soluble in acetic acid. They are often marked on their surfaces with ridges and furrows, and are covered with numerous fibrils, which connect the surfaces of the cells: these are known as *prickle* cells (see page 43). (2) Immediately superficial to these is a single layer of flattened, spindle-shaped cells, the *granular layer*, which contain granules that become deeply stained in hematoxylin, and are composed of a substance termed *eleidin*. They are supposed to be cells in a transitional stage between the protoplasmic cells of the *rete Malpighii* and the horny cells of the superficial layers. (3) Above this layer the cells become indistinct, and appear, in sections, to form a homogeneous or dimly striated membrane composed of closely-packed scales, in which traces of a flattened nucleus

![Fig. 68.—Microscopic section of skin, showing the epidermis and derma; a hair in its follicle; the erector pili muscle; sebaceous and sudoriferous glands.](image-url)
may be found. It is called the stratum lucidum. (4) As these cells successively approach the surface by the development of fresh layers from beneath, they assume a flattened form from the evaporation of their fluid contents, and consist of many layers of horny epithelial scales in which no nucleus is discernible, forming the stratum corneum. These cells apparently become changed in their chemical composition, as they are now unaffected by acetic acid. The deepest layer of the rete Malpighii is separated from the papillae by an apparently homogeneous basement membrane, which is most distinctly brought into view in specimens prepared with chloride of gold. This, according to Klein, is merely the deepest portion of the epithelium, and is "made up of the basis of the individual cells, which have undergone a chemical and morphological alteration." The black color of the skin in the negro and the tawny color among some of the white races is due to the presence of pigment in the cells of the cuticle. This pigment is more especially distinct in the cells of the deeper layer or rete mucosum, and is similar to that found in the cells of the pigmentary layer of the retina. As the cells approach the surface and desiccate, the color becomes partially lost.

The derma, corium, or cutis vera, is tough, flexible, and highly elastic, in order to defend the parts beneath from violence. It varies in thickness, from a quarter of a line to a line and a half, in different parts of the body. Thus it is very thick in the palms of the hands and soles of the feet; thicker on the posterior aspect of the body than the front, and on the outer than the inner side of the limbs. In the eyelids, scrotum, and penis it is exceedingly thin and delicate. The skin generally is thicker in the male than in the female, and in the adult than in the child.

The corium consists of fibrous connective tissue, with a large admixture of elastic fibres and numerous blood-vessels, lymphatics, and nerves. The fibro-areolar tissue forms the framework of the cutis, and is differently arranged in different parts, so that it is usual to describe it as consisting of two layers: the deeper or reticular layer, and the superficial or papillary layer. Unstriped muscular fibres are found in the superficial layers of the corium, wherever hairs are found; and in the subcutaneous areolar tissue of the scrotum, penis, labia majora of the female, and the nipples. In the latter situation the fibres are arranged in bands, closely reticulated and disposed in superimposed laminae. The reticular layer consists of strong interlacing fibrous bands, composed chiefly of the white variety of fibrous tissue, but containing, also, some fibres of the yellow elastic tissue, which vary in amount in different parts, and connective-tissue corpuscles, which are often to be found flattened against the white fibrous tissue-bundles. Toward the attached surface the fasciculi are large and coarse, and the areole which are left by their interlacement are large, and occupied by adipose tissue and sweat-glands. Below this the elements of the skin become gradually blended with the subcutaneous areolar tissue, which, except in a few situations, contains fat. Toward the free surface the fasciculi are much finer, and their mode of interlacing close and intricate.

The papillary layer is situated upon the free surface of the reticular layer; it consists of numerous small, highly sensitive, or vascular eminences, the papillae, which rise perpendicularly from its surface. The papillae are conical-shaped eminences, having a round or blunted extremity, occasionally divided into two or more parts and connected by a thin base with the free surface of the corium. Their average length is about 1/180 of an inch, and they measure at their base 1/250 of an inch in diameter. On the general surface of the body, more especially in those parts which are endowed with slight sensibility, they are few in number, short, exceedingly minute, and irregularly scattered over the surface; but in some situations, as upon the palmar surface of the hands and fingers, upon the plantar surface of the feet and toes, and around the nipple, they are long, of large size, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. In these ridges the larger papillae are arranged in a
double row, with smaller papillae between them; and these rows are subdivided into small square-shaped spaces by short transverse furrows, regularly disposed; in the centre of each of these transverse furrows is the minute orifice of the duct of a sweat-gland. No papillae exist in the grooves between the ridges. In structure the papillae consist of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres. The majority of the papillae contain loops of blood-vessels, and these are known as the vascular papillae in contrast to others which usually possess no blood-vessels, but contain tactile corpuscles. These tactile papillae are most numerous in the derma of the palm of the hand and of the sole of the foot, but occur also in smaller numbers on the back of the hand and foot, on the flexor surface of the forearm, and on the nipple.

The arteries supplying the skin form a network in the subcutaneous tissue, from which branches are given off to supply the sweat-glands, the hair-follicles, and the fat. Other branches are given off which form a plexus immediately beneath the corium; from this fine capillary vessels pass into the papillae, forming, in the smaller papillae, a single capillary loop, but in the larger a more or less convoluted vessel. There are numerous lymphatics supplied to the skin which form two networks, superficial and deep, communicating with each other and with those of the subcutaneous tissue by oblique branches. They originate in the cell-spaces of the tissue.

The nerves of the skin terminate partly in the epidermis and partly in the cutis vera. The former form a dense plexus in the superficial layer of the corium, which extends horizontally and gives off numerous fibrils; these are prolonged into the epidermis, and terminate between the cells, either in bulbous extremities or in a network; or, according to some observers, in the deep epithelial cells themselves. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine the follicle in a circular manner. Other nerve-fibres are supplied to the plain muscular tissues of the hair-muscles (arrectores pili) and to the muscular coat of the blood-vessels. These are probably non-medullated fibres.

The appendages of the skin are the nails, the hairs, the sudoriferous and sebaceous glands, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

The nails are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within, and is implanted by a portion, called the root, into a groove in the skin; the exposed portion is called the body, and the anterior extremity the free edge. The nail has a very firm adhesion to the cutis, being accurately moulded upon its surface, as the epidermis is in other parts. The part of the cutis beneath the body and root of the nail is called the matrix, because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and covered with large, highly vascular papillae, arranged in longitudinal rows, the color of which is seen through the transparent tissue. Behind this, near the root of the nail, the papillae are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter color, and is called the lunula on account of its shape.

The cuticle, as it passes forward on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of its root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails, in structure, consist of cells having a laminated arrangement, and these are essentially similar to those composing the epidermis. The deepest layer of cells, which lie in contact with the papillae of the matrix, are of elongated form, arranged perpendicularly to the
surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely compacted as to make the limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forward and maintains a due thickness, whilst, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new cells, they assume a flattened form, their nuclei become indistinct, and they finally become closely compacted together into a firm, dense, horny texture. In chemical composition the nails resemble epidermis. According to Mulder, they contain a somewhat larger proportion of carbon and sulphur.

The hairs are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, and the penis. They vary much in length, thickness, and color in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in other parts, as upon the scalp, they are of considerable length: again, in other parts, as the eyelashes, the hairs of the pubic region, and the male whiskers and beard, they are remarkable for their thickness. The hairs generally present a cylindrical or more or less flattened form and a reniform outline upon transverse section.

A hair consists of a root, the part implanted in the skin; the shaft or stem, the portion projecting from its surface; and the point.

The root of the hair presents at its extremity a bulbous enlargement, which is whiter in color and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the hair-follicle. When the hair is of considerable length the follicle extends into the subcutaneous areolar tissue. The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inward in an oblique direction to become dilated at its deep extremity, to correspond with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands (Fig. 68). At the bottom of each hair-follicle is a small conical vascular, eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular and supplied with nervous fibrils; this is the part through which material is supplied for the production and constant growth of the hair. In structure the hair-follicle consists of two coats—an outer or dermic, and an inner or epidermic.

The outer or dermic coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and supplied by numerous minute nervous filaments. It consists of three layers (Fig. 69). The most internal, next the cuticular lining of the follicle, consists of a hyaline basement-membrane, having a glassy, transparent appearance, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement-membrane of the surface of the corium. External to this is a layer of spindle-shaped cells, arranged in a circular manner around the follicle and imbedded in a somewhat fibrous matrix, but reaching only as high as the entrance of the ducts of the sebaceous glands. Externally is a thick layer of
connective tissue, arranged in longitudinal bundles, in which are contained the
blood-vessels and nerves.

The inner or epidermic layer is closely adherent to the root of the hair, so
that when the hair is plucked from its follicle this layer most commonly adheres
to it and forms what is called the root-sheath. It consists of two strata, named
respectively, the outer and inner root-sheath; the former of these corresponds with
the Malpighian layer of the epidermis, and resembles it in the rounded form and
soft character of its cells; at the bottom of the hair-follicle these cells become con-
tinuous with those of the root of the hair. The inner root-sheath consists of a
delicate cuticle next the hair; then of one or two layers of horny, flattened,
nucleated cells, known as Huxley's layer; and finally of a single layer of non-
nucleated, horny, flattened cells, called Henle's layer.

The hair-follicle contains the root of the hair, which terminates in a bulbous
extremity, and is excavated so as to exactly fit the papilla from which it grows.
The bulb is composed of polyhedral epithelial cells, which as they pass upward
into the root of the hair become elongated and spindle-shaped, except some in the
centre which remain polyhedral. Some of these latter cells contain pigment-
granules, which give rise to the color of the hair. It occasionally happens that
these pigment-granules completely fill the cells in the centre of the bulb, which
gives rise to the dark tract of pigment often found, of greater or less length, in
the axis of the hair.

The shaft of the hair consists of a central pith or medulla, the fibrous part of
the hair, and the cortex externally. The medulla occupies the centre of the shaft
and ceases toward the point of the hair. It is usually wanting in the fine hairs
covering the surface of the body, and commonly in those of the head. It is more
opaque and deeper colored when viewed by transmitted light than the fibrous part;
but when viewed by reflected light it is white. It is composed of rows of poly-
hedral cells, which contain air-bubbles. The fibrous portion of the hair consti-
tutes the chief part of the shaft; its cells are elongated and unite to form flattened
fusiform fibres. Between the fibres are found minute spaces which contain either
pigment-granules in dark hair or minute air-bubbles in white hair. In addition
to this there is also a diffused pigment contained in the fibres. The cells which
form the cortex of the hair consist of a single layer which surrounds those of
the fibrous part; they are converted into thin, flat scales, having an imbricated
arrangement.

Connected with the hair-follicles are minute bundles of involuntary muscular
fibres, termed arrectores pili. They arise from the superficial layer of the corium,
and are inserted into the outer surface of the hair-follicle, below the entrance of
the duct of the sebaceous gland. They are placed on the side toward which the
hair slopes, and by their action elevate the hair (Fig. 68).

The sebaceous glands are small, sacculated, glandular organs, lodged in the
substance of the corium. They are found in most parts of the skin, but are most
abundant in the scalp and face: they are also very numerous around the apertures
of the anus, nose, mouth, and external ear; but are wanting in the palms of the
hands and soles of the feet. Each gland consists of a single duct, more or less
capacious, which terminates in a cluster of small secreting pouches or sacculae.
The sacculi connected with each duct vary, as a rule, in numbers from two to five,
but, in some instances, may be as many as twenty. They are composed of a
transparent, colorless membrane, enclosing a number of cells. Of these the outer
layer or marginal cells are small, polyhedral, epithelial cells, continuous with the
lining cells of the duct. The remainder of the sac is filled with larger cells, con-
taining fat, except in the centre, where the cells have become broken up, leaving
a cavity containing the débris of cells and a mass of fatty matter, which constitu-
tes the sebaceous secretion. The orifices of the ducts open most frequently into
the hair-follicles, but occasionally upon the general surface. On the nose and face
the glands are of large size, distinctly lobulated, and often become much enlarged
from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.

The **sudoriferous** or **sweat glands** are the organs by which a large portion of the aqueous and gaseous materials are excreted by the skin. They are found in almost every part of this structure, and are situated in small pits in the deep parts of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent duct proceeds upward through the corium and cuticle, becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture. The efferent duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, it is thin, the spiral arrangement does not exist. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is especially distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillae, where they form a thin, mammillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2800 orifices on a square inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and correspond to the small transverse grooves which intersect the ridges of the papillae. In other situations they are more irregularly scattered, but in nearly equal numbers, over parts including the same extent of surface. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and, supposing the aperture of each gland to represent a surface of \( \frac{1}{15} \) of a line in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin. In the larger glands this single duct usually divides and subdivides dichotomously; the smaller ducts ultimately terminating in short cecal pouches, rarely anastomosing. The wall of the duct is thick, the width of the canal rarely exceeding one-third of its diameter. The tube, both in the gland and where it forms the excretory duct, consists of two layers—an outer, formed by fine areolar tissue, and an inner layer of epithelium. The external or fibro-cellular coat is thin, continuous with the superficial layer of the corium, and extends only as high as the surface of the true skin. The epithelial lining in the distal part of the coiled tube of the gland proper consists of a single layer of cubical epithelium, supported on a basement membrane, and beneath it, between the epithelium and the fibro-cellular coat, there is a layer of what are usually regarded as plain muscular fibres, arranged longitudinally. In the duct and the proximal part of the coiled tube of the gland proper there are two or more layers of polyhedral cells, lined on their internal surface—i.e., next the lumen of the tube—by a delicate membrane or cuticle, and on their outer surface by a limiting membrana

![Fig. 72.—Coiled tube of a sweat-gland cut in various directions. a. Longitudinal section of the proximal part of the coiled tube. b. Transverse section of the same. c. Longitudinal section of the distal part of the coiled tube. d. Transverse section of the same. (From Klein and Noble Smith's Atlas of Histology.)](image-url)
properia, but there are no muscular fibres. The epithelium is continuous with the epidermis and with the delicate internal cuticle, which is all that is present in the epidermic portion of the tube. When the cuticle is carefully removed from the surface of the cutis, these convoluted tubes of epithelium may be drawn out and form short, thread-like processes on its under surface.

The contents of the smaller sweat-glands are quite fluid; but in the larger glands the contents are semi-fluid and opaque, and contain a number of colored granules and cells which appear analogous to epithelial cells.

**SEROUS MEMBRANES.**

The **serous membranes** form shut sacs and may be regarded as lymph-sacs, from which lymphatic vessels arise by stomata or openings between the epithelial cells (see page 86). The sac consists of one portion which is applied to the walls of the cavity which it lines—the parietal portion; and another reflected over the surface of the organ or organs contained in the cavity—the visceral portion. Sometimes the sac is arranged quite simply, as the tunica vaginalis testis; at others with numerous involutions or recesses, as the peritoneum, in which, nevertheless, the membrane can always be traced continuously around the whole circumference. The sac is completely closed, so that no communication exists between the serous cavity and the parts in its neighborhood. An apparent exception exists in the peritoneum of the female; for the Fallopian tube opens freely into the peritoneal cavity in the dead subject, so that a bristle can be passed from the one into the other. But this communication is closed during life, except at the moment of the passage of the ovum out of the ovary into the tube, as is proved by the fact that no interchange of fluids ever takes place between the two cavities in dropsy of the peritoneum or in accumulation of fluid in the Fallopian tubes.\(^1\) The serous membrane is often supported by a firm, fibrous layer, as is the case with the pericardium, and such membranes are sometimes spoken of as "fibro-serous."

The various serous membranes are the peritoneum, lining the cavity of the abdomen; the two pleurae and the pericardium, lining the lungs and heart respectively; and the tunicae vaginales, surrounding each testicle in the scrotum.\(^2\) Serous membranes are thin, transparent, glistening structures, lined on their inner surface by a single layer of polygonal or pavement endothelial cells, supported on a matrix of fibrous connective tissue, with networks of fine elastic fibres, in which is contained numerous capillaries and lymphatics. On the surface of the endothelium between the cells numerous apertures or interruptions are to be seen. Some of these are stomata, surrounded by a ring of cubical epithelium (see Fig. 12), and communicating with a lymphatic capillary (see p. 86); others (pseudoosto-
mata) are mere interruptions in the epithelial layer, and are occupied by processes of the branched connective-tissue corpuscle of the subjacent tissue or by accumulations of the intercellular cement-substance.

The secretion of these membranes is, in most cases, only sufficient in quantity to moisten the surface, but not to furnish any appreciable quantity of fluid.\(^3\) When a small quantity can be collected, it appears to resemble in many respects the lymph, and like that fluid coagulates spontaneously; but when secreted in large quantities, as in dropsy, it is a watery fluid, which gives a precipitate of albumen on boiling.

**SYNOVIAL MEMBRANES.**

Synovial membranes, like serous membranes, are connective-tissue membranes placed between two movable tissues, so as to diminish friction, as between the two articular ends of the bones forming a movable joint; between a tendon and a

\(^1\) The communication between the uterine cavity and the peritoneal sac is not only apparent in the dead subject, but is an anatomical fact, which is established by the continuity of its epithelium with that covering the uterus, Fallopian tubes, and fimbrice.

\(^2\) The arachnoid membrane, lining the brain and spinal cord was formerly regarded as a serous membrane, but is now no longer classed with them, as it differs from them in structure, and does not form a shut sac as do the other serous membranes.
bone, where the former glides over the latter; and between the skin and various subcutaneous bony prominences.

The synovial membranes are composed essentially of connective tissue, containing numerous vessels and nerves. It was formerly supposed that these membranes were analogous in structure to the serous membranes, and consisted of a layer of flattened cells on a basement-membrane. No such cells, however, exist, and the only ones found on the surface are irregularly branched connective-tissue corpuscles, similar to those found throughout the tissue. Here and there these cells are collected in patches and present the appearance of epithelium, but do not possess the true characters of an endothelial layer. They are surrounded and held together by an albuminous ground-substance. A further description of the synovial membranes will be found in the descriptive anatomy of the joints.

MUCOUS MEMBRANE.

Mucous membranes line all those passages by which the internal parts communicate with the exterior, and are continuous with the skin at the various orifices of the surface of the body. They are soft and velvety, and very vascular, and their surface is coated over by their secretion, mucus, which is of a tenacious consistency, and serves to protect them from the foreign substances introduced into the body with which they are brought in contact.

They are described as lining the two tracts—the gastro-pulmonary and the genito-urinary; and all, or almost all, mucous membranes may be classed as belonging to and continuous with the one or the other of these tracts.

The external surfaces of these membranes are attached to the parts which they line by means of connective tissue, which is sometimes very abundant, forming a loose and lax bed, so as to allow considerable movement of the opposed surfaces on each other. It is then termed the submucous tissue. At other times it is exceedingly scanty, and the membrane is closely connected to the tissue beneath; sometimes, for example, to muscle, as in the tongue; sometimes to cartilage, as in the larynx; and sometimes to bone, as in the nasal fossae and sinuses of the skull.

In structure a mucous membrane is composed of corium and epithelium. The epithelium is of various forms, including the squamous, columnar, and ciliated, and is often arranged in several layers (see Fig. 11). This epithelial layer is supported by the corium, which is analogous to the derma of the skin, and consists of connective tissue, either simply areolar or containing a greater or less quantity of lymphoid tissue. This tissue is usually covered on its external surface by a transparent structureless basement-membrane, and internally merges into the submucous areolar tissue. It is only in some situations that the basement-membrane can be demonstrated. The corium is an exceedingly vascular membrane, containing a dense network of capillaries, which lie immediately beneath the epithelium, and are derived from small arteries in the submucous tissue.

The fibro-vascular layer of the corium contains, besides the areolar tissue and vessels, unstriped muscle-cells, which form in many situations a definite layer, called the muscularis mucosae. These are situated in the deepest part of the membrane, and are plentifully supplied with nerves. Other nerves pass to the epithelium and terminate between the cells. Lymphatic vessels are found in great abundance, commencing either by cecal extremities or in networks, and communicating with plexuses in the submucous tissue.

Imbedded in the mucous membrane are found numerous glands, and projecting from it are processes (villi and papillae) analogous to the papille of the skin. These glands and processes, however, exist only at certain parts, and it will be more convenient to defer their description to the sequel, where the parts are described as they occur.
SECRETING GLANDS.

The secreting glands are organs whose cells manufacture a secretion of a more or less definite composition, the material for the secretion being primarily selected from the blood. The essential parts, therefore, of a secreting gland are cells, which have the power of extracting from the blood certain matters, and in some cases converting them into new chemical compounds; and blood-vessels, by which the blood is brought into close relationship with these cells. The general arrangement in all secreting structures—that is to say, not only in secreting glands, but also in secreting membranes—is that the cells are arranged on one surface of an extravascular basement-membrane, which supports them, and a minute plexus of capillary vessels ramifies on the other surface of the membrane. The cells then extract from the blood certain constituents which pass through the membrane into the cells, where they are prepared and elaborated. The basement-membrane does not, however, always exist, and any free surface would appear to answer the same purpose in some cases.

By the various modifications of this secreting surface the different glands are formed. This is generally effected by an invagination of the membrane in different ways, the object being to increase the extent of secreting surface within a given bulk.

In the simplest form a single invagination takes place, constituting a simple gland; this may be either in the form of an open tube (Fig. 71, A), or the walls of the tube may be dilated so as to form a sacule (Fig. 71, B). These are named the simple tubular or sacular glands. Or, instead of a short tube, the invagination may be lengthened to a considerable extent, and then coiled up to occupy less space. This constitutes the simple convoluted tubular gland, an example of which may be seen in the sweat-glands of the skin (Fig. 71, C).

If, instead of a single invagination, secondary invaginations take place from

![Diagram of secreting glands]

the primary one, as in Fig. 71, d and e, the gland is then termed a compound one. These secondary invaginations may assume either a saccular or tabular form, and so constitute the two subdivisions—the compound saccular or racemose gland, and the compound tubular. The racemose gland in its simplest form consists of a primary invagination which forms a sort of duct, upon the extremity of which are found a number of secondary invaginations called saccules or alveoli, as in Brunner's glands (Fig. 71, d). But, again, in other instances, the duct, instead of being simple, may divide into branches, and these again into other branches, and so on; each ultimate ramification terminating in a dilated cluster of saccules, and thus we may have the secreting surface almost indefinitely extended, as in the salivary glands (Fig. 71, E). In the compound tubular glands the division of the primary duct takes place in the same way as in the racemose glands, but the branches retain their tubular form, and do not terminate in saccular recesses, but become greatly lengthened out (Fig. 71, F). The best example of this form of gland is to be found in the kidney. All these varieties of glands are produced by a more or less complicated invagination of a secreting membrane, and they are all identical in structure; that is to say, the saccules or tubes, as the case may be, are lined with cells, generally spheroidal or columnar in figure, and on their outer surface is an intimate plexus of capillary vessels. The secretion, whatever it may be, is eliminated by the cells from the blood, and is poured into the saccule or tube, and so finds it way out through the primary invagination on to the free surface of the secreting membrane. In addition, however, to these glands, which are formed by an invagination of the secreting membrane, there are some few others which are formed by an evagination or protrusion of the same structure, as in the vascular fringes of synovial membranes. This form of secreting structure is not nearly so frequently met with.
ORIGIN AND DEVELOPMENT OF THE BODY.

The whole body is developed out of the ovum (Fig. 72) when fertilized by the spermatozoon, the ovum being merely a simple nucleated cell. All the complicated changes by which the various intricate organs of the whole body are formed from one simple cell may be reduced to two general processes—viz. the segmentation or cleavage of cells, and their differentiation. The former process consists in the splitting of the nucleus and its surrounding protoplasm, whereby the original cell is represented by two. The differentiation of cells is a term used to describe that unknown power or tendency impressed on cells which, to all methods of examination now known, seem absolutely identical, whereby they grow into different forms; so that (to take the first instance which occurs in the growth of the embryo) the indifferent cells of the vascular area are differentiated, some of them into blood-globules, others into the solid tissue which forms the blood-vessels. The extreme complexity of the process of develop-

![Diagram of ovum](image.png)

**Fig. 72.—Ovum of the sow.**

ment renders it at all times difficult to describe it intelligibly, and still more so in a work like this, where adequate space and illustration can hardly be afforded, having respect to the main purpose of the work. I can only hope to render the leading features of the process tolerably plain, and must refer the reader who wishes to follow the various changes more minutely to the special works on the subject, and especially the works of Minot and Hertwig. Many of the statements which are accepted in human embryology are made only on the strength of observations on the lower animals, many stages in the development of the human embryo being yet unknown to us.

The ovum is a small spheroidal body situated in immature Graafian vesicles near their centre, but in the mature ones in contact with the membrana granulosa at that part of the vesicle which projects from the surface of the ovary. The cells of the membrana granulosa are accumulated round the ovum in greater number than at any other part of the vesicle, forming a kind of granular zone, the discus proligerus.

The human ovum (Fig. 73) is extremely minute, measuring from \( \frac{1}{2} \) to \( \frac{1}{20} \) of an inch in diameter. It is a cell consisting externally of a transparent envelope, the zona pellucida or vitelline membrane. Within this, and in close contact with it, is the cell-protoplasm containing granules of yolk or vitellus; imbedded in the

\[ ^1 \text{See the description of the ovary at a future page.} \]
substance of the yolk is a small vesicular body, the *germinale vesicle* (vesicle of Purkinje), the nucleus of the cell; and this contains as its nucleolus a small spot, the *macula germinativa*, or *germal spot* of Wagner.

The *zona pellucida*, or *vitelline membrane*, is a thick, colorless, transparent membrane, which appears under the microscope as a radially striated membrane, bounded externally and internally by a dark outline. The striae are believed to be minute pores, and are regarded as the channels by which nutritive particles are admitted into the interior of the ovum, and possibly the way by which the spermatozoa gain access into the interior of the ovum, after the rupture of the Graafian follicle. The presence of these striae has given to the zona pellucida the name of *zona radiata*, or striated membrane of the ovum.

The *yolk* consists of granules or globules of various sizes imbedded in a finely reticulated matrix of protoplasm. The smaller granules resemble pigment; the larger granules, which are in the greatest number at the periphery, resemble fat-globules. In the human ovum the number of granules is comparatively small. Before and immediately after fertilization the cell protoplasm shows distinct movements of contraction and expansion.

The *germinale vesicle* consists of a fine, transparent, structureless membrane containing a clear matrix, in which are occasionally found a few granules. It is about \( \frac{1}{3} \) of an inch in diameter, and in immature ova lies nearly in the centre of the yolk; but as the ovum becomes developed it approaches the surface and enlarges somewhat.

The *germal spot* occupies that part of the periphery of the germinale vesicle which is nearest to the periphery of the ovum. It is opaque, of a yellow color, and finely granular in structure, measuring from \( \frac{1}{3} \) to \( \frac{1}{4} \) of an inch.

The phenomena attending the discharge of the ovum from the Graafian vesicles, since they belong as much or more to the ordinary function of the ovary than to the general subject of the growth of the body, are described with the anatomy of the ovaries on a subsequent page.

Either before its escape from the Graafian follicle or immediately after, the ovum undergoes a peculiar change, which results in the formation of one or more peculiar bodies, the *polar globules* of Robin, and also of another body, which is named the "female pronucleus." The manner in which these bodies are developed from the germinale vesicle is briefly as follows: Usually before the rupture of the Graafian follicle, but after the ovum has become mature or ripe, a portion of the germinale vesicle with a small amount of surrounding protoplasm is protruded outside the yolk, but still remains within the vitelline membrane; this forms a small globular mass and constitutes the first polar globule. After a time, generally not till the ovum has entered the tube, a second protrusion of a portion of the germinale vesicle takes place, and forms a second polar globule. We have thus about three-quarters of the germinale vesicle extruded from the yolk and about one-quarter remaining behind, and at the ejection of each of these bodies a visible shrinking of the yolk takes place. The portion of the germinale vesicle which remains behind recedes from the surface toward the centre of the yolk and assumes a spherical form, and is now termed the "female pronucleus." All these changes, it must be understood, occur at each expulsion of an ovum, and are quite independent of fecundation.

The first changes in the ovum which take place at the time of conception appear to be as follows: A spermatozoa penetrates the ovum, and comes into contact with the portion of the germinale vesicle remaining in the ovum. It seems as if this normally occurs in the Fallopian tube, but it is possible that it sometimes occurs before the ovum has entered the tube, or after it has passed through the tube and reached the cavity of the uterus; abnormally it may even

---

1 Many physiologists, as Bischoff and Dr. M. Barry, taught that the ovum is fecundated in the ovary, but the reasoning of Dr. Allen Thomson appears very cogent in proving that the usual spot at which the spermatozoa meet the ovum is in the tube, down which it slowly travels to the uterus, in its course becoming surrounded by an albuminous envelope derived from the walls of the tube.
take place in the peritoneal cavity. The spermatozoon becomes buried in the yolk, the tail disappears, and the head, which is really the nucleus of the spermatozoon, constitutes the "male pronucleus." This gradually approaches the female pronucleus, which by this time is situated in the centre of the ovum. As soon as they come into contact they fuse into one, and thus fecundation is effected (Fig. 74).  

The first result of the fertilization of the ovum is its cleavage or multiplication, it being first cleft into two masses, the germinal vesicle having previously

1 If the student refers to the development of the generative organs, he will find that the ovum of the female and the spermatozoon of the male are derived from fundamentally the same structures, and therefore their fusion is the union of two elements of very similar morphological value.
SEGMENTATION OF OVUM.

which takes no part in this process of division. Then, each of these two daughter elements divides in like manner, and thus four nucleated elements are formed, and so on, until at length a mulberry-like agglomeration of nucleated masses of protoplasm results (Fig. 75). These masses are sometimes termed segmentation spherules.

The manner in which segmentation occurs is somewhat peculiar. The two spheres resulting from the first cleavage are of unequal size. One, which for the sake of distinction we will call the upper cell, is larger than the other, the lower cell. And after they have divided three or four times the rate of cleavage in the spheres derived from the upper segment becomes more rapid than in those derived from the lower segment. In addition to this, the spheres derived from the upper segment have a tendency to spread over and enclose those from the lower segment; so that by about the ninth or tenth division there is an external layer of spheres derived from the primary upper segment surrounding and almost enclosing a mass of spheres, which in consequence of their diminished rate of cleavage are fewer in number and larger in size, derived from the primary lower segment (Fig. 76, A). Fluid collects between the two sets of spheres, except at one part, where they remain in contact, and the ovum is converted into a sac, formed by a layer of spheres derived from the upper primary segment, and containing at one part another mass of spheres derived from the lower primary segment (Fig. 76, B). The inner cells are rather more granular than the outer, beneath which they gradually spread, becoming applied over a part of their inner surface in a single layer; so that the cavity is afterward enclosed more or less completely in a double layer of cells.

The ultimate destination of the outermost complete layer of spheres is at present doubtful. That portion of it which covers the inner cells is believed to be transitory and to gradually disappear in the course of formation of the various layers of the blastodermic vesicle, while the remainder forms the outer layer (epiblast) of this vesicle. Adopting this view, the ovum would consist of a cavity surrounded by (1) a layer of cells completely lining the interior of the vitelline membrane, and (2) by a second layer internal to these and partially lining the interior of the outer layer, both sets of cells derived from the segmentation of the ovum. The sphere formed by this double layer of cells is called the "blastodermic vesicle."

At first the area of the blastodermic vesicle, which consists of both the inner and outer layers of cells, is a small disk, in which the first traces of the embryo are seen; hence it is called the germinal disk or area germinativa (Fig.

---

**Fig. 76.**—Ovum of the rabbit at the end of the process of segmentation. *oc.* Outer cells, *ic.* Inner cells, *bp.* Place where the outer cells have not yet covered the inner cells. (From Balfour, after Ed. van Beneden.)
DEVELOPMENT.

77). The first trace of the embryo appears as a faint streak at the posterior end of the area germinativa, called the *primitive trace*. After the formation of the primitive trace, but previous to the appearance of the next parts of the embryo, presently to be described—viz. the lamina dorsales and the notochord—the blastodermic membrane consists of only two layers, the *epiblast* and *hypoblast*, but after the formation of these structures a third layer makes its appearance. This is the *mesoblast*, and is situated between the other two (Fig. 77). The epiblast of the germinal disk is formed of the most superficial layers of the inner cells which were exposed by the disappearance of the outer cells, which originally covered them, the remaining epiblast of the blastodermic vesicle being probably the persistent outer cells, while the hypoblast is formed by the rest of the inner cells. In the region of the primitive trace the epiblast and hypoblast fuse together, and from the sides of this line of fusion cells grow out laterally into the space between the epiblast and hypoblast to form the mesoblast, a further formation of this layer also taking place at the margin of the germinal disk. The blastodermic membrane thus comes to consist of three layers: The external, which used to be called the serous layer, but is now more commonly termed the *epiblast*, or *ectodermin*: the internal, the mucous layer, the *hypoblast*, or *entoderm*; and the middle, which is now usually called the *mesoblast* or *mesoderm*, but which was formerly named the "vascular layer."

The *epiblast* is mainly concerned in the formation of the external cuticle and the whole of the nervous system. It consists of cells of an epithelial character; that is to say, cells of an irregular columnar shape, forming, for the most part, a single stratum, but becoming more numerous and flattened at the germinal disk. The epidermis of the body and all the involutions of the epidermis in the ducts of superficial glands, as the mammae, as well as the brain, the spinal cord, the nerves, and the portions of the nose, eye, and ear, which are directly formed from the brain, are developed from it. The external layer of the amnion is also formed from the epiblast, and probably also a portion of the chorion.

The *hypoblast* is mainly concerned in forming the internal epithelium—viz. that of the whole alimentary passages except the mouth and a small portion of the rectum near the anus (which are formed by involutions of the epiblast); that of the respiratory tract, which is originally an offset from the alimentary canal; and the epithelium of all the glandular organs which open into the intestinal tract. The hypoblast forms also the deeper layer of the umbilical vesicle and allantois.

---

![Diagram](image-url)
Its cells are epithelial, and are at first flattened, but subsequently become columnar and larger than those of the epiblast.

All the rest of the embryo is formed from the mesoblast—viz. all the vascular
and locomotive system, the cutis, all the connective tissues, and the genito-urinary organs—with the exception of the epithelium of the bladder and urethra, which is developed from the hypoblast. The vascular system of the foetus extends to the yolk and the maternal parts along the umbilical vesicle and allantois, so that the

*The same note applies to this as to the preceding diagram.*
greater part of these bodies and the outer layer of the amnion are also formed out of the mesoblast. The fetal portion of the placenta, being essentially a vascular structure, is also developed from the mesoblast. Its cells are irregular and branched and surrounded by a considerable amount of intercellular fluid. It may therefore be regarded as resembling more closely embryonic connective tissue.

First Rudiments of the Embryo (Figs. 79 and 80).—The primitive trace alluded to above as appearing in the area germinativa is a very transitory structure, which marks the direction of the embryonic axis, and is gradually lost sight of as development proceeds.

The first real approach toward a definite form in the embryo is made (1) by the development of the central nervous system; (2) by the cleavage of the middle layer of the blastodermic membrane into a series of segments; and (3) by the development of an axial embryonic skeletal structure, the notochord.

First, a folding up of the cells of the epiblast or outer layer takes place. This commences in the anterior part of the area germinativa, and extends in the same direction as the primitive trace, gradually enclosing this latter until it is lost at the caudal extremity of the embryo (Fig. 81). This folding up of the epiblast gives rise to a longitudinal groove down its centre, in consequence of the manner in which the cells of the epiblast are heaped up into two longitudinal ridges, with a furrow between them, so that the sides and base of the groove are formed of epiblastic cells (Fig. 82, 1). The mesoblast, lying between the epiblast and hypoblast, fills up the space thus caused between these two layers, so that the sides of the groove are occupied by a longitudinal thickening of mesoblast; the two masses being separated at the bottom of the groove by the junction of the epiblast and hypoblast at the situation of the primitive trace. The groove becomes deeper and deeper in consequence of the further growing up of the cells to form the ridge on either side. In this way the ridges eventually become two plates, the laminae dorsales or medullary plates, which finally coalesce and thus form a closed tube, the neural canal, lined by epiblast and having a covering of the same membrane (Fig. 82). These membranes are at first in contact with one another, but eventually become separated, mesoblastic structures growing up between them, and the line of coalescence becomes obliterated. The coalescence first takes place in the middle of the embryo, then toward the cephalic end, and lastly at the caudal extremity. The lining of this tube is developed into the nervous centres, the covering into the epidermis of the back and head. The cephalic extremity of the neural canal is soon seen to be more dilated than the rest, and to present constrictions dividing it imperfectly into three chambers: the brain is developed from this dilated portion; the spinal cord takes its origin from the remainder of the tube. Below the neural canal the hypoblast and epiblast are in contact, separating the two longitudinal thickenings of mesoblast on either side of the canal. Here a thickening of the hypoblast, commencing from the anterior end of the primitive trace, takes place, and gradually separates itself off from the hypoblast, lying between this membrane and the epiblast below the bottom of the neural canal. This is known as the notochord or chorda dorsalis. This when fully developed, forms a continuous rod-shaped body lying below the primitive groove and composed of clear epithelium-like cells. It is essentially an embryonic structure, though traces of it remain in the centre of the intervertebral disks throughout life. The collection of mesoblastic cells, which forms a thick longitudinal column on either side of the neural canal, becomes separated from the rest of the mesoblastic layer. It undergoes a series of transverse segmentations and becomes converted into a row of well-defined, dark, square segments or masses, separated by clear, transverse intervals, called the protvertebræ or mesoblastic somites. They first make their appearance in the region which afterward becomes the neck, then further forward toward the head, and afterward extend along the body. These bodies, as will be explained hereafter, are not the same as the permanent vertebrae, but they are differentiated, partly into the vertebrae and partly into the
muscels and true skin. On either side of the protovertebrae the mesoblast splits into two layers, the upper, or that covered by epiblast, is called somatopleure, and the lower, lined by hypoblast, the splanchnopleure (Fig. 82, b, 5-5'). From the

![Diagram](image)

former the skeleton muscles and true skin of the external parts of the body are derived, from the lat-

![Diagram](image)

ter, the muscular and other mesoblastic portions of the vis-
cera. The space between them is the common pleuro-peritoneal cavity. Whilst the parietes of the body are still unclosed, this common pleuro-peritoneal cavity is continuous with the space between the amnion and chorion, as seen in Fig. 79, f. The embryo, which at first seems to be a mere streak, extends longitudinally and laterally. As it grows forward the cephalic end becomes remarkably curved on itself (cephalic flexure), and a smaller but distinct flexure takes place at its hinder end (caudal flexure). At the same time the sides of the embryo grow and curve toward each other; so that the embryo is

In consequence of this incurv-

aptly compared to a canoe turned over (Fig. 83).
ing of the embryo, both in an antero-posterior and a lateral direction, the original ovum, with the three layers derived from the cleavage of the blastodermic membrane which cover it, is converted into a sort of hour-glass shape with two unequal globes. The smaller globe is formed by the part of the blastodermic membrane (area germinativa) which has already undergone certain changes in the formation of the embryo, and constitutes the part which has been compared to a canoe. The larger globe is called the *yolk-sac* or *umbilical vesicle*, and is formed by the rest of the blastodermic membrane—*i.e.* that part which is not concerned in the formation of the area germinativa. The two freely communicate through the constriction which is the site of the future umbilicus, and through this constriction the internal layer of the blastodermic membrane (the hypoblast) and the innermost of the two layers into which, as has been already stated, the mesoblast divides—viz. the splanchnopleure, pass out; the incurring having only involved the somato-pleural layer of the mesoblast and the epiblast (Fig. 84): The umbilical vesicle is, therefore, at first a mere part of the general cavity of the yolk, partly enclosed by the embryo; but as the latter grows round on all sides toward the umbilical aperture, the yolk becomes distinguished into two portions. One lies inside the embryo, and eventually forms a part of the intestinal cavity (out of which also, as will hereafter be seen, the bladder is developed). The other lies external to the embryo and remains therefore for a time a part of what is, in a more restricted sense, the ovum. The two parts are almost separated from each other by the meeting of the abdominal walls of the embryo at the umbilicus, through which they still communicate by a passage, the *omphalo-mesenteric duct*, the destination of which will be pointed out presently. The extra-embryonic portion is of small importance and very temporary duration in the human subject. It is for the purpose of supplying nutrition to the embryo during the very earliest period, before it can obtain it from the uterine sinuses of the mother. In the oviparous animals, however, where no supply of nutrition can be obtained from the mother, since the egg is entirely separated from her, the yolk-sac is large and of great importance, as it supplies nutrition to the chick during the whole of fentation. Vessels developed in the middle blastodermic layer soon cover the umbilical vesicle, forming the *vascular* area, the chief vessels of which are the *omphalo-mesenteric*, two in number (Fig. 85). The vessels of this area appear to absorb the fluid of the umbilical vesicle, which as the fluid is absorbed dries up and has no further function. The activity of the umbilical vesicle ceases about the fifth or sixth week, at the same time that the allantois, which is the great bond
of vascular connection between the embryo and the uterine tissues, is formed. In fact, the umbilical vesicle provides for the nutrition of the fœtus from the ovum itself, while the allantois is the channel whereby it is nourished from the uterine tissues. The umbilical vesicle, containing fluid, remains visible, however, up to the fourth or fifth month, with its pedicle and the omphalo-mesenteric vessels. The latter vessels become atrophied as the functional activity of the body with which they are connected ceases.

So far we have traced—(1) the segmentation or cleavage of the yolk into a number of nucleated cells or “spherules.” (2) The accumulation of fluid within the ovum, and the arrangement of the spherules around the fluid on the internal surface of the vitelline membrane, forming a second membrane, the “blastodermic membrane.” (3) The separation of the blastodermic membrane into three layers, named, from within outward, the “hypoblast,” the “mesoblast,” and the “epiblast.” (4) The formation of an elongated, oval-shaped disk, called the “area germinativa.” (5) The appearance in the centre of the area germinativa of a delicate line or furrow, running longitudinally, and called the “primitive trace.” (6) The formation of a distinct groove in the situation of this primitive trace, caused by the growing-up of the cells on either side of it, so as to form two longitudinal ridges, called the “laminae dorsales.” (7) The increase and incurvation of these laminae dorsales, until they meet behind, enclosing a canal lined by epiblast. The canal is the neural canal, and from the epiblast which lines it the nervous centres are developed. (8) The formation, in the hypoblast immediately under this canal, of a continuous rod-shaped body, the “chorda dorsalis,” or “notochord.” (9) The formation from the mesoblast, on either side of the notochord, of a longi-
tudinal column, divided into a number of square segments, the "protovertebræ." (10) The splitting of the mesoblast, external to the protovertebræ, into two layers—the outer, called the "somatopleure," lined externally by the epiblast; the inner, called the "splanchnopleure," lined internally by the hypoblast, a space being left between the two which forms the "pleuro-peritoneal cavity." (11) The curving of the embryo on itself, both longitudinally and laterally, so as to be comparable to a canoe; the walls being formed of all three layers of the blastodermic membrane and the well of the canoe—that is the intestinal cavity of the embryo, opening into the cavity of the yolk-sac. (12) A portion of the yolk-sac lying in the body-cavity of the embryo, and a portion outside it; the two communicating by a duct, the "omphalo-mesenteric" duct. The portion of the yolk-sac external to the body-cavity is termed the umbilical vesicle, and provides nutrition to the embryo until such time as the placenta is formed; vessels, developed from the middle blastodermic layer, ramifying over it, and gradually absorbing its contents.

The next step toward a clear understanding of the development of the embryo is to have a proper conception of the manner in which the membranes enveloping the fetus are formed.

The membranes investing the foetus are the amnion, the chorion, and the decidua. The two former are developed from foetal structures, and are proper to the fetus; the latter is formed in the uterus, and is derived from the maternal structures.

The Amnion.—The amnion is the membrane which immediately surrounds the embryo. It is of small size at first, but increases considerably toward the middle of pregnancy, as the fetus acquires the power of independent movement. It exists only in reptiles, birds, and mammals, which are hence called "Amniota," but is absent in amphibia and fishes. It is formed thus: At or near the extremities of the incurved fetus—that is to say, at the point of constriction of the blastodermic membrane, where the portion which has undergone changes to form the body of the embryo joins the part devoted to the formation of the umbilical vesicle—an inflection of the epiblast and outer layer of the mesoblast, which have become separated from the inner layer of the mesoblast and hypoblast by the formation of the pleuro-peritoneal cavity, takes place (Fig. 79, d 7). These inflections or back-

---

1 According to Professor John A. Ryder, it is "very doubtful if any considerable amount of nutriment is supplied to the embryo from the yolk-sac at any time."
ward folds commence first at the cephalic extremity, and subsequently at the caudal end and sides, and deepen more and more, in consequence of the sinking of the embryo into the blastodermic vesicle, until, gradually approaching, they meet one another (Fig. 79, F 7). After they come in contact they fuse together, and the septum between them disappears; so that the inner layer of the cephalic fold becomes continuous with the inner layer of the caudal fold, and the outer with the outer (Fig. 79, F 7). Thus we have two membranes, one formed by the inner layer of the fold—the true amnion—which encloses a space over the back of the embryo—the amniotic cavity (Fig. 79, F and G, a)—containing a clear fluid, the liquor amnii.¹ The other, the outer layer of the fold—the false amnion—lines the internal surface of the original vitelline membrane. Between the two is an interval, which of course communicates with the pleuro-peritoneal cavity. This it continues to do until the body-walls of the embryo have grown up and coalesced at the umbilicus. Then the amniotic fold is carried downward, and encloses the umbilical cord, by which the fetus is attached to the placenta. The true amnion—or, as it is usually called, the amnion—is formed of two layers, derived respectively from the epiblast and from the parietal layer of the mesoblast.

The amnion is at first in close contact with the surface of the body of the embryo, but about the fourth or fifth week fluid begins to accumulate, and thus separates the two. The quantity steadily increases up to about the sixth month of pregnancy, after which it diminishes somewhat. The use of the liquor amnii is believed to be chiefly to allow of the movements of the fetus in the later stages of pregnancy, though it no doubt serves other purposes also. It contains about 1 per cent. of solid matter, chiefly albumen, with traces of urea, the latter possibly derived from the urinary secretion of the fetus.

The Chorion.—We have seen that in the formation of the amnion we had two layers formed out of a reduplication of the epiblast and outer layer of the mesoblast: one—the true amnion—which surrounds the embryo and encloses a cavity between it and the embryo—the amniotic cavity; and secondly, the false amnion, which lies in apposition with the internal surface of the vitelline membrane, and is continuous at its periphery with that part of the original epiblast and somatopleural layer of the mesoblast which did not enter into the formation of the area germinativa; and that between these two layers there is a space (which must not be confounded with the amniotic cavity) which communicates with the pleuro-peritoneal space, and, according to Dalton, contains a semifluid, gelatinous material. The chorion is formed out of the vitelline membrane with the false amnion and its peripheral continuation with the external layers of the blastoderm; but the exact share which the three layers take in its formation is at present uncertain. By some embryologists it is believed that the vitelline membrane during the rapid growth of the ovum becomes attenuated, and finally lost; by others it is thought that it combines with the other layers to form the chorion. But, whichever is true, at a very early period of gestation cellular processes or fringes grow outward from the external surface of the chorion, and have been likened by Dalton to tufts of seaweed. They are at first destitute of vessels, and are of simple cellular structure. These fringes, or villi, as they subsequently become, cover at first the whole surface of the chorion; but as development progresses and the placenta, by which the extent of the attachment of the ovum to the uterine walls is to be limited, is about to be formed, the villi are not further developed over the rest of the chorion, but are confined to that part only which is to form the fetal portion of the placenta. They may, however, be recognized all over the chorion as abortive processes during the whole of fetal gestation.

¹ The student should be careful not to confound this cavity with that formed between the true and false amnion, which communicates with the pleuro-peritoneal cavity of the embryo. This latter space ought with more propriety to be called the "amniotic cavity," since it is contained between the layers of the amnion; whereas the so-called amniotic cavity is not really between the layers of the amnion at all, but between the inner layer of the amnion and the body of the embryo.
The Belly Stalk.—During the formation of the amnion the anterior end of the embryo sinks down into the blastodermic vesicle much more rapidly than the posterior end, the latter, in fact, remaining attached to the surface of the blastoderm (Fig. 87, A). As the formation of the amnion proceeds the embryo becomes separated more and more from the surface of the vesicle, eventually being united with it only by a short stalk arising from its ventral surface (Fig. 87, B). This is the "belly stalk," in the interior of which is to be found the umbilical vesicle, which has been carried backward by the constriction which produced the stalk, and has been reduced to a small pyriform vesicle supported upon a long pedicle. This pedicle is connected with the digestive tract of the embryo, and behind its attachment a small outgrowth develops from the ventral wall of the intestine, and, pushing in front of it the splanchnopleure which forms the outer lining of the intestine, extends out into the belly stalk and forms what is known as the allantois. In some animals the allantois is a hollow projection and is usually styled the allantoic vesicle; but in most mammals, and especially in man, the external or mesoblastic element undergoes great development, while the internal or hypoblastic element undergoes little increase beyond the body of the embryo, so that it is very doubtful whether any cavity exists in the allantois beyond the limits of the umbilicus. A portion of the allantoic vesicle within the body cavity is eventually destined to form the bladder, while the remainder forms an impervious cord, the urachus, stretching from the summit of the bladder to the umbilicus. The belly stalk is at first hollow, its cavity being continuous with the pleuro-peritoneal cavity of the embryo (Fig. 87), but it soon becomes solid by the extensive growth of the mesoblastic tissue which it contains. Over that portion of the wall of the blastodermic vesicle with which the outer end of the belly stalk is connected the chorionic villi, already referred to, reach their greatest development, this being the region of the placenta. In the walls of the allantois vessels are formed which extend their branches out into the surrounding mesoblast and into the chorionic villi. The allantois, accordingly, though much reduced in man in comparison with the lower mammals, is still the tract along which the vessels extend which convey the blood of the embryo to the fetal chorion, where it is

1 In some animals some of the vessels of the villi of the chorion are derived from the yolk-sac—that is from the omphalo-mesenteric vessels.
exposed to the influence of the maternal blood circulating in the decidua or uterine portion of the placenta, from which it imbibes the materials of nutrition and to which it gives up effete material, the removal of which is necessary for its purification.

The Decidua.—The growth of the chorion and placenta can only be understood by tracing the formation of the decidua.

The decidua (Figs. 80 a, 88) is formed from the mucous membrane of the uterus. Even before the arrival of the fecundated ovum in the uterus the mucous membrane of the latter is vascular and tumid, and when the ovum has reached the uterus it becomes imbedded in the folds of the mucous membrane, which grow up around it and finally completely encircle it, so as to cover it in entirely and exclude it from the uterine cavity. Thus two portions of the uterine mucous membrane (decidua) are formed—viz. that which coats the muscular wall of the uterus, decidua vera, and that which is in contact with the ovum, decidua reflexa. The decidua vera at the os internum and at the openings of the Fallopian tubes is continuous with the lining membrane of these canals, the thickening of the original mucous membrane of the uterus which converts it into decidua abruptly ceasing at these points. The neck of the uterus after conception is closed by a plug of mucus. The decidua vera is perforated by the openings formed by the enlarged uterine glands, which become much hypertrophied and developed into tortuous tubes. It contains at a later period numerous arteries and venous channels, continuous with the uterine sinuses, and it is from it that the uterine part of the placenta is developed. The portion of the decidua vera which takes part in the formation of the placenta is called the decidua serotina (Fig. 88, f).

The decidual reflexa is shaggy on its outer aspect, but smooth within. The vessels which it contains at first disappear after about the third month. About the fifth or sixth month the space between the two layers of the decidua disappears, and toward the end of pregnancy the decidua reflexa is transformed into a thin yellowish membrane, which constitutes the external envelope of the ovum.

Much additional interest has been given to the physiology of the decidua by the fact, which seems to be now established by the researches of Dr. John Williams, that every discharge of an ovum, whether impregnated or not, is, as a rule, accompanied by the formation of a decidua, and that the essence of menstruation consists in the separation of a decidual layer of the mucous membrane from the uterus; while in the case of pregnancy there is no exfoliation of the
membrane, but, on the contrary, it undergoes further development in the manner described above.

The Placenta is the organ by which the connection between the fetus and mother is maintained. It therefore subserves the purposes both of circulation and respiration. It is formed of two parts, as already shown—viz. the maternal portion, which is developed out of the decidua vera (serotina), and the fetal portion formed out of the villi of the chorion. Its shape in the human subject is that of a disk, one surface of which adheres to the uterine wall, while the other is covered by the amnion. The villi of the chorion gradually enlarge, forming large projections—"cortyledons"—which each contain the ramifications of vessels communicating with the umbilical (allantoic) arteries and veins of the fetus. These vascular tufts are covered with epithelium, and project into corresponding depressions in the mucous membrane (decidua vera) of the uterine wall. The maternal portion of the placenta consists of a large number of sinuses formed by an enlargement of the vessels of the uterine wall. These bring the uterine blood into close proximity with the villi of the fetal placenta, which dip into the sinuses. The interchange of fluids necessary for the growth of the fetus and for the depuration of the blood takes place through the walls of the villi, but there is no direct continuity between the maternal and fetal vessels. The fetal vessels form tufts of capillaries, the blood from which is returned by small veins, which end in tributaries of the umbilical vein. The maternal arteries open into spaces somewhat after the manner of the arteries of the erectile tissues. These spaces communicate with a plexus of veins which anastomose freely with one another, and give rise, at the edge of the placenta, to a venous channel which runs around its whole circumference—the placental sinus.

The umbilical cord is formed by the gradual elongation of the belly stalk. It contains the coils of two arteries (umbilical, originally allantoic), and a single vein, united together by a gelatinous tissue (jelly of Wharton). There are originally two umbilical veins, but one of these vessels becomes obliterated, as do also the two omphalo-mesenteric arteries and veins and the duct of the umbilical vesicle, all of which are originally contained in the belly stalk. The permanent structures of the cord are, therefore, furnished by the allantois.

In this manner the human embryo eventually becomes surrounded by three membranes: (1) the amnion, derived from the outer layer of the mesoblast and the epiblast; (2) the chorion, formed from the false amnion (which is derived from the outer layer of the mesoblast and the epiblast), and (3) the decidua, derived from the mucous membrane of the uterus.

Development of the Embryo proper.—The further development of the embryo will, perhaps, be better understood if we follow as briefly as possible the principal facts relating to the chief parts of which the body consists—viz. the spine, the cranium, the pharyngeal cavity, mouth, etc., the nervous centres, the organs of the senses, the circulatory system, the alimentary canal and its appendages, the organs of respiration, and the genito-urinary organs. The reader is also referred to the chronological table of the development of the fetus at the end of this section.

Development of the Spine.—We have already traced the first steps in the formation of the spine: (1) The looping up of two longitudinal folds from the cells of the epiblast on either side of the primitive streak, so as to form a groove, and the gradual growing together of these ridges (laminae dorsales) so as to convert the groove into a canal, which is lined by epiblast, and out of which the spinal cord is developed. (2) The formation in front of this groove of a continuous cellular cord enclosed in a structureless sheath, the notochord or chorda dorsalis (Fig. 89). The notochord extends from the cephalic to the caudal

---

1 The scope of this work only permits the briefest possible reference to these subjects. Those who wish to study the subject of embryology in more detail are referred to Kölliker's Entwicklungs- geschichte; to vol i. pt. 1, of the tenth edition of Quain's Anatomy; or to the works of Professors Minot and Hertwig.
extremity of the embryo, and lies in the place which is afterward occupied by
the bodies of the vertebrae. (3) On either side of the neural canal a portion of
the mesoblastic layer is divided longitudinally from the rest of the mesoblast,
so as to form a thick column, which extends from the cephalic to the caudal

extremity of the embryo on either side of the spinal canal and notochord (Fig.
82, A 7); this is the protovertebral column. From a part of it is derived the
vertebral column, a considerable portion at the upper and outer part being differ-
etiated from it and eventually forming the muscles of the back. (4) This column
undergoes a process of transverse segmentation and becomes converted into a
number of quadrilateral blocks, the protovertebral somites. The process of seg-
mentation commences in the cervical region and proceeds successively through
the other regions of the body until a number of segments are formed, which corre-
spond very closely to the number of the permanent vertebrae. (5) From each of
these protovertebral somites masses of cells are budded off towards the middle
line, the masses of opposite sides meeting around the notochord, which they
enclose, and extending dorsally around the spinal cord, which they also
enclose. The notochord and the spinal canal are thus surrounded by a cellular
mass derived from the mesoblastic layer, which constitutes the membranous matrix
of the vertebrae. (6) The next step is the conversion of this primitive mem-
branous matrix into cartilage. This takes place probably about the fourth or
fifth week in the human embryo (Kölliker). At intervals along that portion of the
membranous matrix which encloses the notochord the cells become pushed apart
by the formation between them of a homogeneous substance and the tissue
becomes converted into cartilage. The regions which are thus chondrified corre-
spond to the intervals between the successive pairs of protovertebral somites, and
form the bases of the bodies of the future vertebrae, the segments of the spinal
column thus alternating in position with the protovertebral. In the regions oppo-
site each protovertebral somite chondrification does not take place, but the mem-
branous matrix assumes a fibrous structure, forming the intervertebral disks.
Similar changes occur in the portion of the matrix which surrounds the spinal cord. Opposite each vertebral body chondrification takes place, producing the cartilaginous vertebral arches, the intervening tissue becoming transformed into the ligaments which extend between the arches, chiefly the interspinous ligaments and the ligamenta subflava. Below each subflavan ligament an opening is left, through which the spinal nerves make their exit from the spinal canal, the nerves, like the provertebræ, alternating in position with the vertebral centra.

(7) The notochord contained in the centre of this chondrifying mass does not continue to grow, but becomes in the human subject relatively smaller, so as, at last, to form a mere slender thread, except opposite the secondary segmentations; that is to say, corresponding to the intervals between the bodies of the permanent vertebrae. Here it presents thickenings and forms an irregular network, the remains of which are to be found at all periods of life in the central pulp of the intervertebral disks.

**Development of the Ribs and Sternum.**—The ribs are formed by extensions of the blastema of the vertebrae in the mesoblastic layer of the blastodermic membrane. These speedily undergo chondrification, and appear as cartilaginous bars, and become separated from the vertebrae at their posterior extremities. At their anterior ends the costal bars, which are to form the nine upper ribs, turn upward and fuse together so as to form a cartilaginous strip bounding a central median fissure. The strips on either side then join in the middle line from before backward, and so give rise to a longitudinal piece of cartilage, which represents the manubrium and gladiolus of the sternum. In the process of development the sternal attachment of the eighth rib disappears, while that of the ninth sub-divides, one portion remaining attached to the inferior extremity of the cartilaginous sternum and becoming developed into the ensiform cartilage; the other portion reeding from the sternum and becoming attached to the rib above.

The further development of the vertebrae, ribs, and sternum, and the ossification of their cartilaginous structure, are described in the body of the work.

**Development of the Cranium in general, and the Face.**—We have seen that the first trace of the embryo consists in the formation of a longitudinal fold of the epiblast on either side of a median groove, and that these folds or ridges grow backward and meet in the median line, thus forming a canal. This canal, at the cephalic extremity of the embryo, is dilated and forms a bulbous enlargement. The bulbous enlargement soon expands into three vesicular dilatations, which are known as the three primary cerebral vesicles, from which all the different parts of the encephalon are presently to be developed. The most anterior of the three forms the thalamencephalon, whilst a hollow projection from it forms the cerebral hemispheres; the middle one forms the mesencephalon; the posterior the metencephalon and the myelencephalon. The primary cerebral vesicles are at this time, of course, hollow, and their cavities freely communicate with each other at the points of constriction. As the embryo grows, the cerebral vesicles become twice bent forward on their own axis (Figs. 90, 91, A and B).

The upper or posterior curvature is called the cerebral, the lower or anterior, the frontal protuberance.

Thus, we have a triple cavity (see Fig. 91, A, where the three cavities are marked c, me, and m) lined by epiblast and covered by the same structure. Between these two layers of epiblast, a layer of mesoblast, derived from the protovertebral plates of the trunk, is prolonged and spreads over the whole surface of the cerebral vesicles. From these structures the cranium and its contents are developed. The external layer of the epiblast forms the superficial epithelium.
of the scalp. The mesoblastic layer forms the true skin, the blood-vessels, muscles, connective tissue, bones of the skull, and membranes of the brain. The layer of epiblast lining the cavity forms the nervous substance of the encephalon, while the cavity itself constitutes the ventricles.

The upper end of the notochord terminates at its cephalic end in a pointed extremity which extends as far forward as the situation of the body of the future sphenoid bone, and is there imbedded in a mass of tissue, the "investing mass of Rathke." This mass, derived from mesoblastic tissue, becomes cartilaginous, and

from it is developed the basi-occipital and basi-sphenoid bones; and by lateral expansions from it the occipitals, the greater wings of the sphenoid, and the periosteal mass of cartilage surrounding the primary auditory vesicles. From the front of the investing mass of Rathke, which corresponds in position to the future dorsum sellae, two lateral bars are directed forward, enclosing a space which forms the pituitary fossa, in which the pituitary body is eventually developed. These bars are named the trabeculae cranii, and extend as far forward as the anterior extremity of the head, where they coalesce with each other. From them the pre-sphenoid and lateral masses of the ethmoid are developed; and from their coalescence a process is prolonged downward to form a portion of the framework of the face hereafter to be described. From the pre-sphenoids, which are developed from these trabeculae, a lateral expansion takes place, which forms the orbitosphenoid or lesser wings of the sphenoid, enclosing the optic foramen.

The portions of the base of the skull above enumerated are formed from cartilage; the remaining parts, comprising the vault of the skull, are of membranous formation.

The head at first consists simply of a cranial cavity, the face being subsequently developed in the manner now to be described by a series of arches with clefts between them (Fig. 92). On the outer surface of what represents the upper neck region of the embryo four linear vertical grooves make their appearance on each side. Corresponding grooves are also formed in the wall of the intestine, the hypoblast of the pharynx being thus brought into contact with the epiblast of the outer surface of the body along the lines of the grooves. These grooves represent the branchial or visceral clefts, which become actual perforations in the lower vertebrates, and place the cavity of the pharynx in communication with the exterior. On either side of each groove a thickening of the mesoderm occurs, so that five ridges are formed, the first of which is in front of the

first groove, and the last behind the last groove, while the second, third, and fourth are between successive grooves. These are the branchial arches, the first of which has its upper end bent so as to lie at an angle with the lower end, each half of the arch being thus <shaped. The upper limb of the < is termed the maxillary, and the lower, the mandibular process, and between the two there lies a depression, the oral sinus. The outline of this depression is pentagonal, since the ends of the two maxillary processes do not unite, but have projecting down between them a broad plate, the fronto-nasal process. In the mesoblast which occupies the axis of each branchial arch a cartilaginous bar develops, serving as a support for the arch.

The maxillary processes unite with the fronto-nasal process. The latter consists of three plates, a central single one and two lateral ones. The central is called the “mid-frontal” process. It is free in front and below, but behind it is united with the coalesced portion of the trabecule crani, which therefore probably assists in the formation of the septum nasi, and, in addition, of the prominent part of the future nose. The lateral plates of the fronto-nasal process are separated from the central one by a depression or furrow on either side; these furrows form the primary nasal pits or fossae. The lateral plates project downward parallel to the mid-process for a certain distance, and then, curving inward, unite with it, thus shutting off the nasal fossae from the rest of the face. The lateral masses of the ethmoid and lachrymal bones are developed in the lateral plates, and by their union with the mid-frontal process form the intermaxillary bone and the lunula, or central part of the upper lip.

The maxillary processes descend for a short distance, forming the outer wall of the orbit, in which the malar bone is developed; they then incline inward, and, meeting the lateral plate of the fronto-nasal process, form the floor of the orbit, and shut it off from the rest of the face; then, continuing their course downward and inward, they join the mid-frontal process, and with it complete the alveolar arch and the superior maxillary bone. Finally, palatal processes are formed by an extension of the inner sides of this arch; these coalesce with each other in the median line, thus separating the cavity of the mouth from the nasal fossae, and completing the palate. In front, however, the palatal processes do not join with the mid-frontal process, but a cleft is left which constitutes the naso-palatine canal.

The mandibular process forms the lower jaw or mandible, the cartilage which it contains being known as Meckel's cartilage. This becomes ossified, and unites with membrane-bones, developing in the mesoblastic tissue around it, to form the mandibular bone. Its upper end is in contact with the periotic capsule, and from it two portions are separated and ossify to form two of the bones of the middle ear, the malleus and incus. The second arch is named the hyoid arch; from it is formed the styloid process, the stylo-hyoid ligament, and the lesser cornu of the hyoid bone. The third, or thyro-hyoid arch, gives origin to the great cornu of the hyoid bone, while the body of this bone is formed between the second and third arches. The fourth and fifth arches do not reach so great a development as the others, and their cartilages likewise only partially develop.
The lower ends of their cartilages unite together to form the thyroid cartilage of the larynx.

Between the mandibular and maxillary processes the buccal cavity or mouth is formed; this therefore owes its origin to the formation of the processes, and consists of mesoblastic tissue lined by epiblast. As has been already stated (page 108), the cephalic end of the embryo becomes remarkably curved on itself, the fore- and mid-brain bending downward over the anterior portion of the original blastodermic membrane, which remains within the body of the embryo and from which the fore-gut is to be developed. This fore-gut terminates as a blind extremity beneath the head (Fig. 91, A, f). Another prominence forms on the ventral surface of the fore-gut, which represents the rudimentary heart (Fig. 91, A, h). Between these two prominences, caused by the projection of the fore-brain and the heart, an involution of the epiblast takes place, gradually deepening until it comes in contact with the upper part of the alimentary canal. This is the stomodeum or mouth, which becomes bounded by prominences constituting the maxillary and mandibular processes. It is at first quite distinct from the upper part of the alimentary canal, which, as we shall hereafter see, is formed by the inner and splanchno-pleural layer of the mesoblast and the hypoblast, the two cavities being separated by all the layers of the blastodermic membrane. A communication between the two is, however, gradually effected by the absorption of these layers at the anterior extremity of the primitive alimentary cavity and the hinder portion of the epiblastic involution from which the mouth is formed.

The branchial grooves are at first fully exposed on the surface of the neck region of the body, but later a fold of skin grows backward from the lower border of each mandibular process. This fuses below with the side of the body and completely conceals the grooves, which disappear, with the exception of the first. Both the internal and external parts of this persist, the former giving rise to the Eustachian tube and the tympanic cavity, while the upper portion of the latter forms the meatus auditorius.

Development of the Nervous Centres and the Nerves.—The medullary groove above described (page 107) presents, about the third week, three dilatations at its upper end, separated by two constrictions, and at its posterior part another dilatation, called the rhomboidal sinus. Soon afterward the groove become a closed canal (medullary canal), exhibiting corresponding dilatations. This is the rudiment of the cerebro-spinal axis. As the embryo grows, its cephalic part becomes more curved, and the three dilatations at the anterior end of the primitive cerebro-spinal axis become vesicles distinctly separate from each other (Fig. 90). These are the cerebral vesicles—anterior, middle, and posterior. The anterior cerebral vesicle (situated, at this period, quite below the middle vesicle) is the rudiment of the third ventricle, and of the parts surrounding it—viz. the optic thalami and all the parts which form the floor of the third ventricle. The middle vesicle represents the aqueduct of Sylvius, with the corpora quadrigemina. The posterior vesicle is developed into the fourth ventricle, and its walls form the pons Varolii, cerebellum, medulla oblongata, and parts in the floor of the fourth ventricle.

At an early period in the development of this primitive brain a protrusion takes place from the anterior vesicle, which is at first simple, but soon becomes divided into two parts by an antero-posterior fissure. These expand laterally, and the cerebral hemispheres and corpora striata are developed from them. In the roof of the fore-part of the posterior cerebral vesicle a thickening takes place, forming the rud-
ment of the cerebellum. In consequence of these protrusions or outgrowths taking place, the three primary cerebral vesicles are now converted into six permanent rudiments of the brain and medulla oblongata. The anterior part of the original anterior cerebral vesicle (fore-brain, prosencephalon), now divided into two, constitutes the cerebral hemispheres, corpus callosum, corpora striata, fornix, lateral ventricles, and olfactory bulbs. The hemispheres are at first relatively small and do not conceal the parts formed from the middle primary vesicle or the optic thalami, which with the optic nerves, the third ventricle, and the parts in its floor, are furnished by the posterior portion of the anterior vesicle (inter-brain, thalamencephalon). By the third month, however, the hemispheres have risen above the optic thalami, and by the sixth month above the cerebellum. Fissures are seen on the surface of the hemispheres at the third month, but all except one disappear. This one persists, and forms the fissure of Sylvius. The permanent fissures for the convolutions do not form till about the seventh or eighth month. The middle cerebral vesicle (mid-brain, mesencephalon) is at first situated at the summit of the angle shown on Fig. 90. Its smooth surface is soon divided, by a median and transverse groove, into four tubercles (tubercula quadrigemina), which are gradually overlapped by the growth of the cerebral hemispheres. Its cavity diminishes as its walls thicken, and contracts to form the aqueduct of Sylvius. The crura cerebri are also formed from this vesicle. The third primary cerebral vesicle at an early period (between the ninth and twelfth week) consists of the hind-brain or metencephalon, forming the cerebel- lum, pons Varolii, and anterior part of the fourth ventricle, and of the after-brain or myelencephalon, which forms the medulla oblongata with the rest of the fourth ventricle.

The development of the pituitary body has of late received much attention. It is mainly formed by a diverticulum from the buccal involution of epiblast. At its upper and front part this involution, from which the mouth or stomodeum is developed, forms a hollow saccular protrusion, which extends into the angle formed by the bend of the fore-with the mid-brain. Here it comes in contact with a median hollow protrusion, which passes downward and backward from the posterior portion of the anterior cerebral vesicle (Fig. 91, c. if). They become intimately connected, and together form the pituitary body or hypophysis.

When the medullary groove is first closed, the foetal spinal cord occupies its whole length, and presents a large central canal, which gradually contracts in consequence of the thickening and rapid growth of the epiblast around it. This increase in thickness takes place principally at the sides, so that eventually the central canal acquires on section the appearance of a slit. The two sides of this slit eventually join in the middle, and the original canal is divided into two: an anterior, which becomes the central permanent canal, which in after life is no longer perceptible to the eye, though it is still visible on microscopic section; and a posterior, which becomes filled about the ninth week with a septum of connective tissue from the pia mater, and forms the posterior fissure of the cord. The anterior fissure is formed simply as a cleft left between the lateral halves of the cord.

After the fourth month the spinal column begins to grow in length more rapidly than the medulla spinalis, so that the latter no longer occupies the whole canal. The cord is composed at first entirely of uniform-looking cells, which soon separate into two layers, the inner of which is composed of cells which increase by division, and develop outgrowths which become axis-cylinders of nerve-fibres. These cells are termed neuroblasts. The cells of the outer layer, known as spongioflaets, scatter themselves among the neuroblasts, forming the neuroglia cells, some of them migrating inwards to form the ependymal lining of the cavities of the cord and brain.

The cerebral and spinal membranes are, according to Kölliker, a production from the protovertebral somites, and are recognizable about the sixth week. As the fissures separating the segments of the cerebro-spinal axis appear, the mem-
branches extend through them and the pia mater passes into the cerebral ventricles.

The Nerves.—The nerves are developed, like the rest of the nervous system, from epiblast. The spinal nerves are developed as follows: Close to the point of involution of the epiblast in the median line—that is to say, in the angle of junction of the neural and general epiblast—a cellular swelling constituting the neural crest appears, and forms a continuous ridge on the dorsal aspect of the neural canal. On this crest enlargements occur, corresponding with the middle of each protovertebral segment. These grow downward between the neural canal and the mesoblastic tissue forming the protovertebrae, and occupy a position on the lateral wall of the canal. These enlargements are the rudiments of the ganglion of the posterior root; they are at first attached to the neural crest from which they spring, but subsequently this attachment becomes lost, and they then form isolated masses on either side of the neural canal, which now contains the rudimentary cord. They consist of oval cells, from either end of which a process eventually springs; one, passing centrally, grows into the embryonic cord and constitutes the posterior root of the nerve; the other, growing peripherally, joins the fibres of the anterior root to form the spinal nerve.

The anterior root is, according to the researches of His, a direct outgrowth of certain cells which are found in the rudimentary cord, and which are named neuroblasts. These cells, like those mentioned above, are oval, and have a prolongation directed outward toward the surface of the cord. These processes pass out of the cord in bundles and penetrate the mesoblast and join with fibres of the posterior root, and from the point of union the nerve grows toward its peripheral termination.

Most of the cranial nerves are developed in the same manner as the posterior roots of the spinal nerves. That is to say, the neural crest, developed from the epiblast, is continued onward, along the dorsal surface of the cephalic portion of the neural tube, as far as the mid-brain. From this a series of swellings at irregular intervals form the rudimentary ganglia, from the polar cells of which the nerve is formed and its connection with the brain established. This appears to be the case with the sensory portion of the fifth, the portion of the facial connected with the geniculate ganglion, the auditory and the sensory portions of the glossopharyngeal and pneumogastric. The motor portions of the mixed nerves and the third, fourth, sixth, spinal accessory and hypoglossal arise like the anterior roots of the spinal nerves from neuroblasts in the floor of the aqueduct of Sylvius and of the fourth ventricle.

The olfactory tract and bulb is a protrusion of the antero-ventral part of each cerebral hemisphere. This protrusion comes in contact with the thickened epiblast of the olfactory area (see page 125), from which neuroblastic cells, which are formed within the area, pass out and form a ganglion between the area and the olfactory bulb. From this ganglion cell-processes grow centripetally to form the nerve-roots, and centrifugally to form the olfactory nerves which ramify on the Schneiderian membrane.

The optic nerve arises in a manner somewhat different from any of the other cranial nerves. It will be considered in connection with the development of the eye.

The sympathetic nerves are probably developed as outgrowths from the ganglia of the spinal and cranial nerves.

Development of the Eye.—The nervous elements and non-vascular parts of the eye are formed from the epiblast, and the vascular portions from the mesoblast; but the method of development is somewhat complicated. The essential portion of the eye—i.e. the retina and the parts immediately connected with it—is an outgrowth from the rudimentary brain (primitive ocular vesicle), and this outgrowth is met by an ingrowth from the common epidermic or corneous layer of the epiblast, out of which the lens and the conjunctival and corneal epithelium are developed.
THE EYE.

The first appearance of the eye consists in the protrusion or evagination from the medullary wall of the thalamencephalon, or inter-brain, of a vesicle, called the primitive ocular vesicle. This is at first an open cavity communicating by a hollow stalk with the general cavity of the cerebral vesicle. As the primitive ocular vesicle is prolonged forward, it meets the epidermic layer of the epiblast, which at the point of contact becomes thickened, and then forms a depression which gradually encroaches on the most prominent part of the primitive ocular vesicle, which in its turn appears to recede before it, so as to become at first depressed and then inverted in the manner indicated by the annexed figure (Fig. 94, a), so that the cavity is finally almost obliterated by the folding back of its anterior half, and the original sac converted into a cup-shaped cavity, the ocular cup, in which the involuted epiblastic layer, the rudiment of the lens, is received (Fig. 94, b). This cup-shaped cavity consists therefore of two layers: one, the outer, originally the posterior half of the primitive ocular vesicle, is thin, and eventually forms the pigmented layer of the retina; the other layer, the inner, originally the anterior or more prominent half, which has become folded back, and is much thicker, is converted into the nervous layers of the retina. Between the two are the remains of the cavity of the original primary vesicle, which finally becomes obliterated by the union of its two layers. The optic nerve fibres originate from the cells of the ganglionic layer of the retina, which thus correspond to the cells of the posterior root ganglia of the spinal nerves. From these cells the fibres grow toward the brain, choosing the optic stalk as a path along which to grow, the stalk thus becoming gradually replaced by the optic nerve. As development proceeds the cup-shaped cavity or ocular cup increases in size, and thus a space is formed between it and the rudimentary lens which it contains; this is the secondary ocular vesicle, and in it the vitreous humor is developed (Fig. 94, c). The folding in of the primary optic vesicle to produce the optic cup proceeds from above downward, and gradually surrounds the lens, but leaves an aperture or fissure below, the choroidal fissure or ocular cleft, through which vascular elements, within the vesicle and derived from the mesoblast, retain their connection with the rest of the mesoblast. This gap or cleft is continued for some distance into the stalk of the optic vesicle, and thus allows a process of the mesoblast to extend down the stalk to form the arteria centralis retinae and its accompanying vein. The lens is at first a thickening of the epiblast; then a depression or involution takes place, thus forming an open follicle, the margins of which gradually approach each other and coalesce, forming a cavity enclosed by epiblastic cells

\[1\] This layer forms functionally part of the choroid, and was formerly described as belonging to this membrane; it is now described as part of the retina, on account of its method of development.
(Fig. 94). At the point of involution the external layer of epiblast separates from the ball of the lens and passes freely over the surface, so that the lens becomes disconnected from the epiblastic layer from which it was developed, and recedes into the ocular cup, while the cuticular layer covering it is developed into the corneal epithelium. The cells forming the posterior or inner wall of the cavity, which is to form the lens, rapidly increase in size, becoming elongated and developed into fibres, and, filling up the cavity, convert it into a solid body. The cells on the anterior wall undergo no change and retain their cellular character. The secondary ocular vesicle, or space between the lens and the hollow of the ocular cup (Fig. 94, c 7, and 95), contains a quantity of mesoblastic tissue continuous through the ocular cleft with the rest of the mesoblast, and into this blood-vessels project themselves through the ocular cleft. The iris and ciliary processes are formed from this vascular tissue, and the choroid is developed in the mesoblast surrounding the ocular vesicle. A portion of this tissue also becomes converted into the vitreous humor, and surrounds the lens with a vascular membrane—the vascular capsule of the lens, which is connected with the termination of the temporary artery (hyaloid) that forms the continuation of the central artery of the retina through the vitreous chamber. This vascular capsule of the crystalline lens forms the membrana pupillaris (described on a subsequent page), and also attaches the borders of the iris to the capsule of the lens. It disappears about the seventh month.

The eyelids are formed at the end of the third month as small cutaneous folds, which come together and unite in front of the globe and cornea. This union is broken up and the eyelids separate before the end of fetal life.

The lachrymal canal develops as a thickening of the epiblastic cells at the bottom of the groove which extends upward toward the eye between the maxillary and the fronto-nasal processes. The thickening becomes hollowed out into a canal, and the lips of the groove meet over it, thus removing it from the surface.

Development of the Ear.—The first rudiment of the ear appears shortly after that of the eye, in the form of a thickening of the epiblast, on the outside of that part of the third primary cerebral vesicle which eventually forms the medulla oblongata, opposite the dorsal end of the second pharyngeal arch. The thickening is then followed by an involution of the epiblast, which becomes deeper and deeper, sinking toward the base of the skull, and a flask-shaped cavity is formed; by the narrowing of the external aperture the neck of the flask constitutes the recessus labyrinthi. The mouth of the flask then becomes closed, and thus a shut sac is formed, the primitive auditory or otic vesicle, which by its sinking inward comes to be placed between the ali-sphenoid and basi-occipital matrices. From it the internal ear is formed. The middle ear and the Eustachian tube are developed from the remains of the first branchial cleft, while the pinna and external meatus are developed from the soft parts overhanging the posterior margin of the same cleft. The primary otic vesicle becomes imbedded in a mass of mesoblastic tissue, which rapidly undergoes chondrification and ossification. It, as before stated, is at first flask- or pear-shaped, the neck of the flask, or recessus labyrinthi, prolonged backward, forms the aqueductus vestibuli. From it are given off certain prolongations or diverticula, from which the various parts of the labyrinth are formed. One from the anterior end gradually elongates, and, forming a tube bends on itself from left to right and becomes the cochlea. Three others, which appear on the surface of the vesicle, form the semicircular canals. Subsequently, a constriction takes place in the original vesicle, which, gradually increasing, divides it into two, and from these are formed the utricle and saccule. Finally, the auditory nerve, which has been developed from the "neural crest" in the manner above described (page 122), pierces the auditory capsule in two main divisions—one for the vestibule, the other for the cochlea. The middle ear and Eustachian tube are the remains of the first pharyngeal or branchial cleft (hyo-mandibular), and are, from an early period, closed by the formation of the membrana tympani, which consists of a layer of epiblast externally, a layer of hypoblast internally, and between the two of mesoblastic tissue consti-
tuting its fibrous and vascular layer. With regard to the exact mode of development of the ossicles of the middle ear there is considerable difference of opinion. The malleus and incus, however, seem to be developed from the proximal end of the mandibular (Meckel's) cartilage, while the stapes seems to have a double origin, its plate being an ossification of the cartilage which fills the foramen ovale in the embryonic condition, while its arch is an ossification of the upper end of the cartilage of the hyoid arch.

The external auditory meatus is developed, like the pinna, from the soft parts on the posterior margin of the first visceral cleft by an outgrowth of the tissues in this situation.

Development of the Nose.—The olfactory fosse, like the primary auditory vesicles, are formed in the first instance by a thickening and involution of the epiblast, which takes place at a point below and in front of the ocular vesicle (Fig. 92, 2, 3). The thickening appears at a very early period, about the fourth week. The borders of the involuted portion very soon become prominent, in consequence of the development of the mid-frontal and lateral naso-frontal plates above spoken of (page 119), which are formed on either side of the rudimentary fosse. As these processes increase the fosse deepen and become converted into a deep channel, which eventually forms the upper part of the nasal fossæ—that is, the two superior meatuses, the part to which the olfactory nerves are distributed. At this time they are continuous with the buccal cavity, a portion of which forms the lower part, or inferior meatus of the nasal fossæ. For as the palatine septum is formed the buccal cavity is divided into two parts, the upper of which forms the lower part of the nasal fossæ, while the remainder forms the permanent mouth.

The soft parts of the nose are formed from the coverings of the frontal projections and of the olfactory fosse. The nose is perceptible about the end of the second month. The nostrils are at about the third month closed by the growth of their epithelium, but this condition disappears about the fifth month.

The olfactory nerve, as above pointed out, is formed from the anterior cerebral vesicle as a secondary vesicle on its under surface, and it lies upon the involuted epiblast, which subsequently forms the nasal fossæ.

Development of the Skin, Glands, and Soft Parts.—The epidermis is produced from the external, the true skin from the middle, blastodermic layer (Fig. 79, 19, 20). About the fifth week the epidermis presents two layers, the deeper one corresponding to the rete mucosum. The subcutaneous fat forms about the fourth month, and the papillæ of the true skin about the sixth. A considerable desquamation of epidermis takes place during foetal life, and this desquamated epidermis, mixed with a sebaceous secretion, constitutes the vernix caseosa, with which the skin is smeared during the last three months of foetal life. The nails are formed at the third month, and begin to project from the epidermis about the sixth. The hairs appear between the third and fourth months in the form of depressions of the deeper layer of the epithelium, which then become inverted by a projection from the papillary layer of the skin. The papillæ grow into the interior of the epithelial layer; and finally, about the fifth month, the foetal hairs (lanugo) appear first on the head and then on the other parts. These hairs drop off after birth, and give place to the permanent hairs. The cellular structure of the sudoriferous and sebaceous glands is formed from the epithelial layer, while the connective tissue and blood-vessels are derived from the mesoblast about the fifth or sixth month. The mammary gland is also formed: partly from mesoblast—its blood-vessels and connective tissue; and partly from epiblast—its cellular elements. Its first rudiment is seen about the third month, in the form of a small projection inward of epithelial elements, which invade the mesoblast; from this similar tracts of cellular elements radiate; these subsequently give rise to the glandular follicles and ducts. The development of the former, however, remains imperfect, except in the adult female.

Development of the Limbs.—The upper and lower limbs begin to project, as
buds, from the anterior and posterior part of the embryo about the fourth week. These buds are formed by a projection of the somatopleure (i.e., the outer layer of the mesoblast and the epiblast), from the point where the mesoblast splits into its parietal and visceral layers, just external to the vertebral somites, of which they may be regarded as lateral extensions. The division of the terminal portion of the bud into fingers and toes is early indicated, and soon a notch or constriction marks the future separation of the hand or foot from the forearm or leg. Next, a similar groove appears at the site of the elbow or knee. The indifferent tissue or blastema, of which the whole projection is at first composed, is differentiated into muscle and cartilage before the appearance of any internal cleft for the joints between the chief bones.

The muscles become visible about the seventh or eighth week. They are derived from the protovertebral somites, and are consequently at first arranged in segments, a condition which is retained by some of the deeper muscles of the back and by the intercostal muscles. Fusion of successive segments takes place, however, and further differentiation of the muscular sheet thus formed into a varying number of muscular bundles brings about the adult condition. The muscles of the limbs are produced from outgrowths from the protovertebral somites in the regions in which the limb buds appear.

Development of the Blood-vascular System.—There are three distinct stages in the development of the circulatory system before it arrives at its complete or adult condition, in accordance with the manner in which nourishment is provided for at different periods of the existence of the individual. In the first stage there is the vitelline circulation, during which nutriment is extracted from the yolk or contents of the vitelline membrane. In the second stage there is the placental circulation, which commences after the formation of the placenta, and during which nutrition is obtained by means of this organ from the blood of the mother. In the third stage there is the complete circulation of the adult, commencing at birth, and during which nutrition is provided for by the organs of the individual itself.

1. The vitelline circulation is carried on partly within the body of the embryo and partly external to it in the vascular area of the yolk. It consists of a median tubular heart, from which two vessels (arteries) project anteriorly. These carry the blood to a plexus of capillaries spread over the area vasculosa, and also, though to a less extent, in the body of the embryo. From this plexus the blood is returned by two vessels (veins) which enter the heart posteriorly, and thus a complete circulation is formed.

In these vessels and the heart a fluid (blood) is contained, in which rudimentary corpuscles are found. The mode of formation of these elementary parts will have first to be considered.

In mammalia the heart is formed as a longitudinal fold of the splanchnopleure on either side of the median line in front of the anterior extremity of the rudimentary pharynx, at about the level of the posterior primary cerebral vesicle, the folds projecting dorsally into the celom. The walls of the folds thicken and present two distinct strata of cells; the inner and thinner layer forms the endocardium, the outer and thicker the muscular wall of the heart. In its very earliest and primitive condition the heart consists, therefore, of a pair of tubes, one on either side of the body. These, however, soon coalesce in the median line, and, fusing together, form a single central tube.1 Each of the two primary tubes receives posteriorly a large vessel (a vein), and is prolonged anteriorly into a second vessel (an artery). So that after fusion of the heart-tubes has taken place, there is, in the primitive vitelline circulation, as above mentioned, a single tubular heart, with two arteries proceeding from it and two veins emptying themselves into it. The earliest vessels are also formed in the visceral emptying layer of the mesoblast. They are developed from that part of the mesoblast which surrounds the portion of blastoderm which is occupied by the developing body of the

1 In most fishes and in amphibia the heart originates as a single median tube.
THE BLOOD-VASCULAR SYSTEM.

127

embryo, and which is known as the "vascular area." So that the first blood-vessels are developed outside the body of the embryo. Some of the cells of which the vascular area is composed arrange themselves in cords, the cords forming a network. Fluid begins to collect in the interior of the cords, forcing apart the cells of which they are composed, and converting them into canals, some of the cells collecting here and there into groups adherent to the walls of the canals and projecting into their lumen. These are the so-called "blood-islands" (Fig. 96, c), and the cells which compose them separate later on and become the embryonic blood-corpuscles. The blood-vessels early extend in toward the embryo from the vascular area, the new vessels arising as bud- or spur-like outgrowths from those already existing. Eventually, the vasifactive process reaches the embryo and the developing vessels come into contact and communicate with the heart, which by this time has been formed and is already pulsating before the vessels reach it.

The earliest embryonic red blood-corpuscles are all nucleated and are more properly termed blood-cells, true blood-corpuscles, which in all the mammalia are non-nucleated, making their appearance about the second month of development and gradually replacing the embryonic blood-cells. The origin of the corpuscles is somewhat uncertain; some embryologists believe them to be formed from the blood-cells by the extrusion of the nuclei of the latter, while others maintain that they are special formations developing in the protoplasm of the red blood-cells and being thus from the beginning non-nucleated. In later life the formation of red corpuscles seems to occur in the marrow of the bones. The white corpuscles or leucocytes appear very early in development, but their exact origin is not known; probably they arise from the mesoblastic tissue outside the blood-vessels and migrate into their interior. The vitelline circulation commences about the fifteenth day and lasts till the fifth week. When fully established it is carried on as follows: Proceeding from the tubular heart are two arteries, the first aortic arteries (Fig. 97), which unite at some distance from the heart into a single artery. This runs down in front of the primitive vertebrae and behind the walls of the intestinal cavity, and again divides into two primitive aortae or vertebral arteries, and these give off five or six omphalo-mesenteric arteries, which ramify in that part of the blastoderm which surrounds the developing body of the embryo, and which is known as the vascular area. They terminate peripherally in a circular vessel—the terminal sinus. This vessel surrounds the vascular portion of the germinal area, but does not extend up to the anterior end of the embryo. It terminates on either side in a vein called the omphalo-mesenteric. The two omphalo-mesenteric veins open into the opposite extremity of the heart to that from which the arteries proceeded.

2. The Placental Circulation.—As the umbilical vesicle diminishes, the allantois and the placenta develop in the manner already indicated. When the umbilical vesicle disappears the latter becomes the only source of nutrition for the embryo. The allantois carries with it to the placenta two arteries, derived from branches of the primitive aorta, and two veins; these vessels become much enlarged as the placental circulation is established, but subsequently one of the veins disappears, and in the later stages of uterine life the circulation is
carried on between the foetus and the placenta by two arteries and one vein (umbilical).

During the occurrence of these changes great alterations take place in the primitive heart and blood-vessels, above alluded to, which will now require description.

Further Development of the Heart.—The simple median tube, formed by the coalescence of the pair of tubes of which the primitive heart consists, becomes elongated and bent on itself, so as to form an S-shaped tube, the anterior part of the tube bending over to the right, and the posterior to the left. At the same time the middle portion is protruded forward and arches transversally from right to left and at the same time becomes twisted on itself, so that the extremity from which the arteries are prolonged is situated in front and to the right, and that into which the veins enter is behind and to the left. The bent tube then becomes divided by two transverse constrictions into three parts. One, the posterior, becomes the auricles, the middle one forms the two ventricular cavities, while the anterior forms the aortic bulb, from which the commencement of the aorta and pulmonary artery is developed. A division of each of these cavities now takes place, so as to convert them into right and left ventricle, right and left auricle, and aorta and pulmonary artery respectively. In the middle portion of the tubular heart, the rudimentary ventricular cavities (Fig. 97, a, 5), a partition rises up from the lower part of the right wall of this cavity, and gradually grows up until it reaches the constrictions which separate it from the other two, and thus the interventricular septum is completed. At the same time a cleft appears on the outside, a little to the right of the most prominent point, which ultimately becomes the apex of the heart. The cleft becomes less marked as development progresses, but remains to some extent persistent throughout life as the interventricular groove.

The first appearance of a division in the posterior or auricular portion of the tubular heart makes its appearance, at a very early period of development, in the shape of two projecting pouches, one on either side; these are the rudiments of the auricular appendages, but the actual division of the cavity by a septum does not occur until some time later. This is formed by the growth of a partition from the anterior wall of the auricular cavity, which grows backward, and partially separates the cavity into two. The partition, however, is not completed until after birth, a part remaining undeveloped, and thus permitting of a communication (foramen ovale) between the two auricles during the whole of foetal life. In a like manner the aortic bulb is divided into two by the growth of a septum downward, from the distal end of the bulb, which divides the cavity into the permanent aorta and the pulmonary artery, and, uniting below with the upper edge of the interventricular septum, places the aorta in communication with the left, and the pulmonary artery with the right ventricle. Very soon a superficial furrow appears on the external surface of this portion of the heart corresponding to the septum internally, and, becoming deeper, the two vessels are gradually separated from each other through the septum, in the immediate neighborhood of the ventricular portion of the heart, whilst beyond this they still remain joined together, and give origin to the fourth and fifth aortic arches, presently to be described.

Further Development of the Arteries.—In the vitelline circulation two arteries were described as coming off from the primitive heart, and running down in front of the developing vertebrae. The first change consists in the fusion of these arteries into one at some distance from the heart, thus forming the descending
thoracic and abdominal aorta. In consequence of the heart falling backward to the lower part of the neck and then into the thorax as the head is developed, the two original arteries, proceeding from the heart to the point of fusion in the common descending aorta become elongated, and assume an arched form, curving backward on each side, from the front of the body toward the vertebral column (Fig. 98, a). These are the first or primitive aortic arches. As the heart recedes into the thorax, and these arches, which correspond in position to the first pharyngeal or mandibular arch, become elongated, four pairs of arches are formed behind

FIG. 98.—Diagram of the formation of the aortic arches and the large arteries. 1, II, III, IV, V. First, second, third, fourth, and fifth aortic arches. A. Common trunk from which the first pair spring; the place where the succeeding pairs are formed is indicated by dotted lines. B. Common trunk, with four arches and a trace of the fifth. C. Common trunk, with the three last pairs, the first two having been obliterated. D. The persistent arteries, those which have disappeared being indicated by dotted lines. 1. Common arterial trunk. 2. them around the pharynx (Fig. 98). The arches, five in number, remain permanent in fishes, giving off from their convex borders the branchial arteries to supply the gills. In many animals the five pairs do not exist together, for the first two have disappeared before the others are formed; but this is not so in man, where all five arches are present and pervious during a certain period of embryonic existence. Only some of the arches in mammalia remain as permanent structures; other arches, or portions of them, become obliterated or disappear. The first two arches entirely disappear. The third remains as a part of the internal carotid artery, the remainder being formed by the upper part of the posterior aortic root—i.e., the descending part of the original vessel which proceeded from the rudimentary tubular heart. The common and external carotid are formed from the anterior aortic root; that is, the ascending portion of the same primitive vessel. The fourth arch on the left side becomes developed into the permanent arch of the aorta in mammals; but in birds it is the fourth arch on the right side which forms the aortic arch; while in reptiles the fourth arch on both sides persists, as there is a permanent double aortic arch. The fourth arch on the right side forms the subclavian artery, and by the junction of its commencement with the anterior aortic root, from which the common carotid is developed, it forms the innominate artery.1 The fifth arch on the left side forms the pulmonary artery and the ductus arteriosus; that on the right side becomes atrophied and disappears. The first part of the fifth left arch remains connected with that part of the bulbous aorta which is separated as the pulmonary stem, and with it forms the common pulmonary artery. From about the middle of this arch two branches are given off, which form the right and left pulmonary arteries respectively, and the remaining portion—i.e., the part beyond the origin of the branches, communicating with the left fourth arch, that is, the descending part of the arch of the aorta—constitutes the ductus arteriosus. This duct remains pervious during the whole of fetal life, and after birth becomes obliterated.

The development of the arteries in the lower part of the body is going on during the same time. We have seen that originally there were two primitive arteries coming off from the primary tubular heart, and that these two vessels, at some

1 This is interesting in connection with the position of the recurrent laryngeal nerve, which is thus seen to hook round the same primitive fetal structure, which becomes on the right side the subclavian artery, on the left the arch of the aorta.
distance from the heart, became fused together to form a single median artery, which coursed down in front of the vertebrae to the bottom of the spinal column, forming the permanent descending aorta. From the extremity of this the two vitelline arteries, which were originally parts of the primitive main trunks, pass to the area vasculosa. As the umbilical vesicle dwindles and the allantois grows, two large branches are formed as lateral offshoots of the median aorta. These are the two umbilical or hypogastric arteries, and are concerned in the placental circulation. The portion of the median aorta beyond this point becomes much diminished in size, and eventually forms the sacra media artery, and thus the two umbilical branches become in appearance bifurcating branches of the main aorta. The common and internal iliac arteries are developed from the proximal end of these umbilical arteries; the middle portion of the vessel, after birth, becomes partially atrophied, but in part remains pervious as the superior vesical artery; the distal portion becomes obliterated, constituting part of the superior ligament of the bladder. The external iliac and femoral arteries are developed from a small branch given off from the umbilical arteries near their origin, and are at first of comparatively small size.

Development of the Veins.—The formation of the great veins of the embryo may be best considered under two groups, visceral and parietal.

The visceral are derived from the vitelline and umbilical veins. In the earliest period of the circulation of the embryo, we have seen that there were two veins (vitelline or omphalo-mesenteric) returning the blood from the vitelline membrane. These unite together to form a single channel, the sinus venosus, which opens into the auricular extremity of the heart. As soon as the placenta begins to be formed two umbilical veins appear and open into the sinus venosus, close to the vitelline veins. The two vitelline veins enter the abdomen and run upward on either side of the intestinal canal; at the upper part of the abdomen, in the site of the future liver, which now begins to form around them, transverse communications are formed, which encircle the duodenum and enclose it in two vascular rings. The
portion of veins above these vascular rings loses its connection with the sinuses, while the portion between them breaks up into a capillary plexus, which ramifies in the now partially developed liver together with capillary vessels from the upper venous ring. Of these latter, some pass toward the heart and join the sinus. They have received the name of the *venae hepaticae recehentes*, and eventually become the hepatic veins; others ramify in the liver, under the name of *venae hepaticae adhehentes*, and become the branches of the portal vein. The lower vascular ring receives veins from the stomach and intestines, and becomes the commencement of the portal vein.

The umbilical veins at first open into the sinus venosus near to the vitelline veins. Subsequently this communication becomes interrupted by the develop-

![Diagram](image-url)

**Fig. 100.—Diagrams illustrating the development of the great veins.** The first figure shows the cardinal veins emptying into the heart by twolateral trunks, "the ducts of Cuvier." The second figure shows the formation of the vena cava and the union of the left iliac with the right cardinal. *a.* Inferior vena cava. *b.* Left innominate vein. The third figure shows the cardinal veins much diminished in size and the duct of Cuvier, on the left side, gradually diminishing. *c.* Vena azygos minor. The fourth figure shows the adult condition of the venous system. *1.* Right auricle of heart. *2.* Vena cava superior. *3.* Jugular veins. *4.* Subclavian veins. *5.* Vena cava inferior. *6.* Iliac veins. *7.* Lumbar veins. *8.* Vena azygos major. *9.* Vena azygos minor. *10.* Superior intercostal vein. *11.* Coronary sinus, the remains of the left duct of Cuvier. (Modified from Dalton.)

ment of a vascular network; the vein on the right side atrophies and disappears, while that on the left side greatly enlarges, as the placental circulation becomes established, and communicates with the upper venous circle of the vitelline circulation. Finally a branch is formed between the upper venous circle and the right hepatic veins, which becomes the *ductus venosus*, and by it most of the blood from the umbilical vein is carried direct to the heart.

The Parietal Veins.—The first appearance of a parietal system consists in the appearance of two short transverse veins (the *ducts of Cuvier*), which open on either side of the auricular portion of the heart. Each of these ducts is formed by an ascending and descending vein. The ascending veins return the blood from the parietes of the trunk and the Wolffian bodies, and are called *cardinal* veins. The two descending ones return the blood (Fig. 100) from the head, and are called *primitive jugular* veins. The cardinal veins receive the blood returning from the lower limb through the iliac veins. At first the right and left iliac veins open into the corresponding cardinals, but later a connecting vein forms between the lower portions of the cardinals, and through this the blood of the left iliac flows over to join the right cardinal. At the same time a large venous trunk, which receives the blood from the kidneys, forms along the middle line of the posterior abdominal wall and unites below with the right cardinal and above with the common trunk of the vitelline and umbilical veins above the point of entrance of the *venae recehentes*. This is the inferior vena cava. A portion of the right cardi-
nal, above the point of junction of the vena cava, becomes obliterated, the upper portion, which receives some of the lumbar and the intercostal veins, persisting as the vena azygos major; while the left cardinal, separating below from the left iliac, sends a branch across the middle line of the body to form a communication with the azygos major and persists as the azygos minor.

The veins first formed in the upper part of the trunk are, as above stated, the primitive jugular veins. In the greater part of their extent they become the internal jugular vein. Shortly, two small branches may be noticed opening into them near their termination; these form the subclavian veins. From the point of junction of these veins on the left side, a communicating branch makes its appearance, running obliquely across the neck downward and to the right, to open into the primitive jugular vein of the right side below the point of entrance of the subclavian vein. At the same time, in consequence of the alteration in the position of the heart, and its descent into the thorax, the direction of the ducts of Cuvier becomes altered, and they assume an almost vertical position. From the portion of the primitive jugular veins, above the branch of communication, the internal jugulars are formed, except that part of the right one which lies between the point of entrance of the subclavian of this side and the termination of the communicating branch, which becomes the right innominate vein. The communicating branch becomes the left innominate vein. The primitive jugular of the right side, below the communicating vein, and the right duct of Cuvier, become the vena cava superior, into which the right cardinal (vena azygos major) enters. The lower part of the left primitive jugular becomes almost entirely obliterated, except at its lower end, where it remains as a fibrous band, or sometimes a small vein, and runs obliquely over the posterior surface of the left auricle. The termination of the left duct of Cuvier remains persistent, and forms the coronary sinus (Fig. 100), the left cardinal separating from it and emptying its blood through the transverse connecting branch into the vena azygos major. The foetal circulation is described at a future page.

Development of the Alimentary Canal.—The development of the intestinal cavity is, as shown above (page 109), one of the earliest phenomena of embryonic life. The original intestine consists of an inflexion of the hypoblast extending from one end of the embryo to the other, and is situated just below the primitive vertebral column. At either extremity it forms a closed tube, in consequence of the cephalic and caudal flexures (page 109), and this manifestly divides it into three parts; a front part, enclosed in the cephalic fold, called the fore-gut; a posterior part, enclosed in the caudal fold, the hind-gut; and a central part or mid-gut,

which at this time freely communicates with the umbilical vesicle (Fig. 101). The ends of the fore- and hind-gut do not communicate with the surface of the body, the buccal and anal orifices being subsequently formed by involutions of the epiblast, which later on form communications with the gut. From the fore-gut
are developed the pharynx, oesophagus, stomach, and duodenum; from the hind-gut, a part of the rectum; and from the middle division, the rest of the intestinal tube (Figs. 102 and 103). The changes which take place in the fore-gut are as follows: The middle portion becomes dilated to form the stomach, and undergoes a vertical rotation to the right, so that the posterior border, by which it is attached to the vertebral column by a mesentery, is now directed to the left, and the anterior border to the right. At this time it is straight, but it soon undergoes a lateral curve or bend to the right at its upper end. It thus assumes an oblique direction, and the left border (originally the posterior or attached border) becomes inferior, and forms the great curvature. The mesentery by which it was attached forms the great omentum. The portion of the fore-gut above this dilatation remains straight, forming the pharynx and oesophagus, while the part below the dilated stomach forms the duodenum, and in connection with this the liver and pancreas are developed.

The hind-gut is also a closed tube, and from it the middle third of the rectum is developed, as well as the allantois (page 118), which will be again referred to in connection with the development of the bladder.

The mid-gut is at first an open cavity freely communicating with the umbilical vesicle. As the body-walls grow, this communication contracts very materially, though it still exists to a certain extent, and the open cavity becomes converted into a straight tube, still open where it communicates with the umbilical vesicle. This tube grows rapidly in length, and presents a primitive curve or loop downward and forward, and, in consequence of its growth exceeding that of the walls of the body-cavity, a portion of the loop protrudes into the stalk of the umbilical vesicle. At a subsequent period, however, the walls of the abdomen grow more rapidly than the intestine, which again recedes into the body-cavity. At a short distance below the most prominent point of this loop a diverticulum arises, which marks the separation between the large and small intestine. The lower part of this diverticulum forms the vermiform appendix; the proximal part, by its continued growth, constitutes the cecum. After this the anterior or upper part of the gut, corresponding to the small intestine, rapidly increases in length, and about the eighth week becomes convoluted. The lower or posterior part, corresponding to the large intestine, is at first less in calibre than the upper part, and lies wholly to the left side of the convolutions of the small intestine; but later on the curve of the large intestine begins to form, and the first part (ascending colon) slowly crosses over to the right side, first lying in the middle line, just below the liver. It is not until the sixth month that the cecum descends into the right iliac fossa, and so drags the ascending colon into its normal position in the right flank.

The peritoneal cavity is the space left between the visceral and parietal layers of the mesoblast, and the serous membrane is developed from these structures. The mesenteries are formed from mesoblastic tissue extending between the vertebrae and the gut which develops the vascular and connective-tissue elements of these parts.

The buccal cavity is formed by an involution of the external layers of the blastodermic membrane, which passes inward and meets the pharynx, or upper part of the fore-gut. The two cavities are, however, at first completely separated from each other by all the layers of the blastoderm; but at an early period of
development a vertical slit appears between them; this gradually widens and becomes the opening by which the common cavity of the nose and mouth communicates with the pharynx. The common cavity is afterward divided into nose and mouth by the development of the palate, in the manner spoken of above.

The tongue appears about the fifth week as a small elevation behind the inferior maxillary arch, to which a pair of elevations, arising from the junction of the third and fourth pharyngeal arches, is united. The line of union of the three elevations is indicated by the V-shaped groove in which the circumvallate papillae are situated. The epithelial layer is furnished by the epiblast. The tonsils appear about the fourth month.

The anus is also formed by an inflection of the epiblast, which extends inward to a slight extent, and approaches the termination of the hind-gut and finally communicates with it by a solution of continuity in the septum between the two. The persistence of the foetal septum at either the buccal or anal orifices constitutes a well-known deformity—imperforate oesophagus or imperforate rectum, as the case may be.

The liver appears after the Wolffian bodies, about the third week, in the form of a bifid process, projecting from the intestine at that part which afterward forms the duodenum. This process grows rapidly, its terminal lobes branching abundantly to form a complicated tubular gland. The duct of the gland becomes the main duct of the liver, while the lobes become transformed into the right and left lobes of the liver and surround the vitelline and, later, the umbilical veins, which break up into a capillary plexus and ramify in their substance. About the third month the liver almost fills the abdominal cavity. From this period the relative development of the liver is less active, more especially that of the left lobe, which now becomes smaller than the right; but the liver remains up to the end of foetal life relatively larger than in the adult.

The gall-bladder appears about the second month, as an extension of the cavity from which the main duct of the liver is developed; and bile is detected in the intestines by the third month.

The pancreas is also an early formation, being far advanced in the second month. It, as well as the salivary glands, which appear about the same period, originates in a projection from the hypoblastic canal, which afterward forms a cavity, and the lobules of the gland are developed from the ramifications of this cavity. The projection for the pancreas appears on the dorsal wall of the intestine, while that for the liver is on the ventral surface, and the ducts of the two glands are at first usually separated. During development the duct of the pancreas shifts its position toward the ventral surface and finally, as a rule, joins that from the liver.

The spleen is entirely of mesoblastic origin, as it originates from the mesenteric fold which connects the stomach to the vertebral column (mesogastrium).

Development of the Respiratory Organs.—The lungs appear somewhat later than the liver. They are developed from a small median cul-de-sac or diverticulum from the upper part of the fore-gut, immediately behind the fourth visceral gleft, as a projection from the epithelial and fibrous laminae of the intestines. During the fourth week a pouch is formed on either side of the central diverticulum, and opens freely through it into the fore-gut (pharynx). From these, other (secondary) pouches are given off, so that by the eighth week the form of the lobes of the lungs may be made out. The two primary pouches have thus a common pedicle of communication with the pharynx. This is developed into the trachea (Fig. 97, ii), the cartilaginous rings of which are perceptible about the seventh week. The parts which afterward form the larynx are recognized as early as the sixth week—viz. a projection on either side of the pharyngeal opening, which is the rudiment of the arytenoid cartilage and a transverse elevation from the third pharyngeal arch, which afterward becomes the epiglottis; the vocal cords and ventricles of the larynx are seen about the fourth month. Traces of the diaphragm appear in the form of a fine membrane, separating the lungs
from the Wolffian bodies, the stomach, and the liver, whilst the heart is still near the head. As the diaphragm extends forward from the vertebral column it separates the common pleuro-peritoneal cavity into two parts, a thoracic and abdominal.

**Development of the Urinary Organs.**—Three distinct sets of urinary organs occur in the embryo at different periods of development, two of them being more or less transitory, while the third becomes the permanent kidney. The first to appear is the **pronephros** or head-kidney and it consists of a small number of somewhat convoluted tubules which develop immediately behind the heart in the mesoblast of certain of the protovertebral somites. The tubules are segmentally arranged, one corresponding to each protovertebra, and they communicate at one extremity with the coelom and at the other with a longitudinal canal known as the **segmental** or Wolffian duct. Later the second kidney appears below the pronephros, developing in a similar manner and forming the **mesonephros** or Wolffian body, whose tubules are also at first arranged segmentally, though later they become more numerous than the protovertebrae from which they arise, by the formation of secondary and tertiary tubules by budding from those already present. These tubules likewise communicate with the Wolffian duct, and in connection with each of them there is developed a little knot of blood-vessels which projects into the lumen of the tubule, whose wall it pushes in front of it, and forms the **Malpighian body** or **glomerulus**. The third and last kidney to appear is the **metanephros** or permanent kidney, which, together with the ureter, arises as an outgrowth from the lower end of the Wolffian duct.

The Wolffian duct is perceptible about the third week, forming an elongated ridge of cells situated on either side of the primitive vertebrae and extending from the heart to the lower end of the embryo. It makes its appearance below the heart and behind the common pleuro-peritoneal cavity, from the mesoblast at the point of separation of its two layers into somatopleure and splanchnopleure, this portion of the mesoblast being termed the "intermediate cell mass." The ridge is at first solid, but soon a tube is hollowed out in it, and continuing to develop posteriorly it unites with the proximal end of the allantois which forms what is termed the urogenital sinus. Thus a communication is established through the Wolffian tubes and ducts between the pleuro-peritoneal cavity and the cloaca or hinder part of the alimentary canal. The next step is the formation of a second duct in the neighborhood of the original duct, with which some of the tubules of the anterior part of the segmental body (pronephros) are connected. This is the Müllerian duct. The ureter, which is formed later, is, as has been described, an offshoot from the hinder part of the Wolffian duct.

The structure of the Wolffian body is in many respects analogous to that of the permanent kidney (Fig. 104). It is composed partly of an excretory canal or duct, into which open numerous "conduits," rectilinear at first, but afterward tortuous, and partly of a cellular or glandular structure, in which Malpighian tufts are found. It is fixed to the diaphragm by a superior ligament, and to the spinal column by an inferior or inguinal ligament. Its office is the same as that of the kidneys—viz. to secrete fluid containing urea, which accumulates in the bladder. When the permanent kidneys are formed, the greater part of the Wolffian body disappears. The rest takes part in the formation of the organs of generation.

The functional activity of the Wolffian bodies is very transitory; they attain their highest development by the sixth
week, after which time they begin to decrease in size and have nearly disappeared by the end of the third month. The upper part of the segmental body, the pronephros, also undergoes atrophy and disappears. In the male, the Wolffian duct persists, and becomes converted into the vas deferens, the Müllerian duct undergoing atrophy, a vestige of it, however, remaining as the sinus prostaticus; whereas, on the other hand, in the female, the Müllerian duct remains and becomes converted into the whole length of the genital passages, while the Wolffian duct almost entirely disappears and remains only as a vestige. Prior to this, however, the Wolffian and Müllerian ducts (together with the ureter when formed) open into the common urogenital sinus referred to above, and which on its part communicates with the terminal portion of the intestinal cavity which is known as the cloaca (Fig. 105).

As the allantois expands into the urinary bladder this common cavity is divided into two by a septum, and the urogenital sinuses then communicate with the anterior division and the rectum with the posterior. The Wolffian and Müllerian ducts are soon connected by cellular substance into a single mass—the genital cord—in which the Wolffian ducts lie side by side in front, and the ducts of Müller behind, at first separate, but later on uniting with each other.

It has been stated that the kidney (metanephros) is developed from the lower part of the Wolffian duct. It commences as a tubular diverticulum from the lower part of the segmental duct, close to the cloaca. It extends upward, and becomes divided into a number of cecal tubules, which represent the commencement of the several divisions of the pelvis of the kidney. These tubules are prolonged into a solid mesoblastic blastema situated near the lower end of the mesonephros. The tubules then become convoluted, and masses of cells accumulate on their exterior, so as to give to the organ an appearance of lobulation. Between these cells vessels are developed, and the vascular glomeruli are gradually formed. The kidneys at first, therefore, consist of cortical substance only, but later on the proximal ends of the tubes become straight and arranged in bundles, and thus the pyramidal structure is developed. The lobulation of the kidney is perceptible for some time after birth.

The urinary bladder, as before stated, is formed by a dilatation of the lower part of the stalk of the allantois. At the end of the second month this forms a spindle-shaped cavity, the bladder, which communicates with the lower part of the primitive intestine by a short canal, the urogenital sinus, which becomes the first part of the urethra. The upper part of the stalk of the allantois, which is not dilated, forms the urachus; this extends up into the umbilical cord, and at an early period of embryonic existence forms a tube of communication with the allantois. It is obliterated before the termination of fetal life, but the cord formed by its obliteration is perceptible throughout life, passing from the upper part of the bladder to the umbilicus, and it occasionally remains patent in the adult, constituting a well-known malformation.

The suprarenal bodies are developed from two different sources. The medul-
lary part of the organ is of epiblastic origin, and is derived from the tissues forming the sympathetic ganglia of the abdomen, while the cortical portion is of mesoblastic origin, and originates in the mesoblast just above the kidneys. The two parts are at first quite distinct, but become combined in the process of development. The suprarenal capsules are at first larger than the kidney, but become equal in size about the tenth week, and from that time decrease relatively to the kidney, though they remain, throughout foetal life, much larger in proportion than in the adult.

Development of the Generative Organs.—The first appearance of the reproductive organs is essentially the same in the two sexes, and consists in a thickening at one spot of the epithelial layer which lines the peritoneal or body cavity, with a slight increase of the connective tissue beneath it, forming a low ridge. This is termed the genital ridge, and is situated on the mesial side of each Wolffian body, and from it the testicle in the one sex, and the ovary in the other, are developed. The ridge, as the embryo grows, gradually becomes pinched off from the Wolffian body, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the mesorchium or mesovarium. About the seventh week the distinction of sex begins to be perceptible. The epithelium on the genital ridge, which is called "germ-epithelium," in the female becomes distinctly columnar, multiplies rapidly, and begins to form primitive ova, in a manner presently to be described; whereas in the male, though the germ-epithelium has a tendency to become columnar, the cells are, on the whole, flatter and smaller than in the female.

Development of Male Organs.—The tubuli seminiferi of the testicle appear at an early period. It is believed that they are formed by the extension of epithelial cells on the surface of the genital ridge into the connective tissue or stroma on which they rest; rows of cells are thus developed which become the lining cells of the seminal ducts. From the mesonephros tubules grow toward the kidney, entering into relation with the seminal ducts and forming the tubuli recti and rete testis, through which the semen escapes from the testis and passes into the tubules of the upper part of the mesonephros, which persist as the epididymis, and thence make their way to the urethra (urogenital sinus) by the Wolffian duct, which becomes the vas deferens and ejaculatory duct of the adult.

The Müllerian ducts disappear in the male sex, with the exception of their lower ends. These unite in the middle line, and open by a common orifice into the urogenital sinus. This constitutes the uterus masculinus or sinus prostaticus. Occasionally, however, the upper end of the duct of Müller remains visible in the male, constituting the little pedunculated body, called the hydatid of the epididymis, sometimes found in the neighborhood of the epididymis, between the testes and globus major.

It has been seen that the upper portion of the mesonephros and the Wolffian ducts persist. The rest of the mesonephros disappears almost entirely, a few of its tubules forming the vas aberrans and a structure described by Giraldeus, and called, after him, "the organ of Giraldeus," which bears a good deal of resemblance to the organ of Rosenmüller in the other sex. It consists of a number of convoluted tubules lying in the cellular tissue in front of the cord, and close to the head of the epididymis.

The descent of the testis and the formation of the gubernaculum are described in the body of the work.

Development of Female Organs.—The ovary, as above stated, is formed from the genital ridge, which becomes pinched off from the remains of the Wolffian body, but is still attached by a mesovarium. It consists of a central part of connective tissue covered by a layer of germ-epithelium, from which the ova are developed. This epithelium undergoes repeated division, so that it rapidly increases.

1 Mr. Osborn, in the St. Thomas's Hospital Reports, 1875, has written an interesting paper pointing out the probable connection between this fetal structure and one form of hydrocele.
in thickness and forms several layers. Next certain of the cells become enlarged and spherical, and form what are called the primitive ova. Around these, other epithelial cells have a tendency to arrange themselves, so as to enclose the ovum in a follicle. The permanent ova, enclosed in their Graafian follicles, are thus formed.

The Fallopian tube is developed from that portion of the duct of Müller which lies above the lumbar ligament of the Wolffian body. This duct is at first completely closed at its upper extremity, and its closed extremity remains permanent, forming a small cystic body attached to the fimbriated end of the Fallopian tube, and called the "hydatid of Morgagni." Below this a cleft forms in the duct, and is developed into the fimbriated opening of the Fallopian tube.

Below this the duct of Müller and the ducts of the Wolffian bodies are united together in a structure called "the genital cord," in which the two Müllerian ducts approach each other, lying side by side, and finally coalesce to form the cavity of the vagina and uterus. This coalescence commences in the middle of the genital cord, and corresponds to the body of the uterus. The upper parts of the Müllerian ducts in the genital cord constitute the cornua of the uterus, little developed in the human species. The only remains of the Wolffian body in the complete condition of the female organs are two rudimentary or vestigial structures, which can be found, on careful search, in the broad ligament near the ovary; the parovarium or organ of Rosenmüller and the paroophoron (Fig. 106).
organ of Rosenmüller consists of a number of the tubules of the upper part of the Wolffian body, and, consequently, is homologous with the epididymis of the male, while the paroöphoron is formed by a few persistent tubules of the lower part of the body, corresponding, therefore, to the organ of Giraldès and the vas aberrans of the male. The lower portions of the Wolffian ducts also persist in the form of a pair of tube-like structures, found one on each side in the walls of the uterus and termed the ducts of Gärtnér. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. The round ligament is derived from the inguinal ligament of the Wolffian body, the peritoneum constitutes the broad ligament; the superior ligament of the Wolffian body disappears with that structure (Fig. 107).

The external organs of generation, like the internal, pass through a stage in which there is no distinction of sex (Fig. 108, II, III). We must therefore
DEVELOPMENT.

describe this stage, and then follow the development of the female and male organs respectively.

As stated above, the anal depression at an early period is formed by an involution of the external epithelium, and the intestine is still closed at its lower end. When the septum between the two opens, which is about the fourth week, the allantois in front and the intestine behind both communicate with the anal depression. This, which is now called the cloaca, is afterward divided by a vertical septum, whose lower edge thickens to form the perineum, and which appears about the second month. Two tubes are thus formed; the posterior becomes the lower part of the rectum, the anterior has uniting with it the urogenital sinus. In the sixth week a tubercle, the genital tubercle, is formed in front of the cloaca, and this is soon surrounded by two folds of skin, the genital folds. Toward the end of the second month the tubercle presents, on its lower aspect, a groove, the genital furrow, turned toward the cloaca. All these parts are well developed by the second month, yet no distinction of sex is possible.

Female Organs (Fig. 108, A, B, C).—The female organs are developed by an easy transition from the above. The portion of the cloaca in front of the septum persists as the vestibule of the vagina, and forms a single tube with the upper part of the vagina, which, as we have already seen, is developed from the united Müllerian ducts. The genital tubercle forms the clitoris, the genital folds the labia majora, and the lips of the genital furrow the labia minora, which remain open.

Male Organs (Fig. 108, A', B', C').—In the male the changes are greater. The genital tubercle is developed into the penis, the glans appearing in the third month, the prepuce and corpora cavernosa in the fourth. The genital furrow closes and thus forms a canal, the spongy portion of the urethra. The urogenital sinus becomes elongated and forms the prostatic and membranous urethra. The genital folds unite in the middle line to form the scrotum, at about the same time as the genital furrow closes—viz. between the third and fourth months.

The following table is translated from the work of Beaunis and Bouchard, with some alterations, especially in the earlier weeks. It will serve to present a résumé of the above facts in an easily accessible form.¹

¹ It will be noticed that the time assigned in this table for the appearance of the first rudiment of some of the bones varies in some cases from that assigned in the description of the various bones in the sequel. This is a point on which anatomists differ, and which probably varies in different cases.
CHRONOLOGICAL TABLE
OF
THE DEVELOPMENT OF THE FETUS.
(FROM BEAUNIS AND BOUCHARD.)

First Week.—During this period the ovum is in the Fallopian tube. Having been fertilized in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus probably about the end of the first week. During this time it does not undergo much increase in size.

Second Week.—The ovum rapidly increases in size and becomes imbedded in the decidua, so that it is completely enclosed in the decidua reflexa by the end of this period. An ovum believed to be of the thirteenth day after conception is described by Reichert. There was no appearance of any embryonic structure. The equatorial margins of the ovum were beset with villi, but the surface in contact with the uterine wall and the one opposite to it were bare. In another ovum, described by His, believed to be of about the fourteenth day, there was a distinct indication of an embryo. There was a medullary groove bounded by folds. In front of this a slightly prominent ridge, the rudimentary heart. The amnion was formed and the embryo was attached by a stalk, the allantois, to the inner surface of the chorion. It may be said, therefore, that these parts, the amnion and the allantois, and the first rudiments of the embryo, the medullary groove, and the heart, are formed at the end of the second week.

Third Week.—By the end of the third week the flexures of the embryo have taken place, so that it is strongly curved. The protovertebral disks, which begin to be formed early in the third week, present their full complement. In the nervous system the primary divisions of the brain are visible, and the primitive ocular and auditory vesicles are already formed.

The primary circulation is established. The alimentary canal presents a straight tube communicating with the yolk-sac. The pharyngeal arches are formed. The limbs have appeared as short buds. The Wolffian bodies are visible.

Fourth Week.—The umbilical vesicle has attained its full development. The caudal extremity projects. The upper and the lower limbs and the cloacal aperture appear. The heart separates into a right and left heart. The special ganglia and anterior roots of the spinal nerves, the olfactory fossae, the lungs and the pancreas can be made out.

Fifth Week.—The allantois is vascular in its whole extent. The first traces of the hands and feet can be seen. The primitive aorta divides into aorta and pulmonary artery. The duct of Müller and genital gland are visible. The ossification of the clavicle and the lower jaw commences. The cartilage of Meckel occupies the first post-oral arch.

Sixth Week.—The activity of the umbilical vesicle ceases. The pharyngeal clefts disappear. The vertebral column, primitive cranium, and ribs assume the cartilaginous condition. The posterior roots of the nerves, the membranes of the nervous centres, the bladder, kidney, tongue, larynx, thyroid body, the germs of teeth, and the genital tubercle and folds are apparent.

Seventh Week.—The muscles begin to be perceptible. The points of ossification of the ribs, scapula, shaft of humerus, femur, tibia, palate, and upper jaw appear.

Eighth Week.—The distinction of arm and forearm, and of thigh and leg, is apparent, as well as the interdigital clefts. The capsule of the lens and pupillary membrane, the interventricular and commencement of the interauricular septum, the salivary glands, the spleen, and suprarenal capsules are distinguishable. The larynx begins to become cartilaginous. All the vertebral bodies are cartilaginous. The points of ossification for the ulna, radius, fibula, and ilium make their appearance. The two halves of the hard palate unite. The sympathetic nerves are now for the first time to be discerned.

Ninth Week.—The corpus striatum and the pericardium are first apparent. The ovary and testicle can be distinguished from each other. The genital furrow appears. The cartilaginous nuclei of the bodies and arches of the vertebrae, of the frontal, vomer, and malar bones of the shafts of the metacarpal and metatarsal bones, and of the phalanges appear. The union of the hard palate is completed. The gall-bladder is seen.

Third Month.—The formation of the fissural placenta advances rapidly. The projection of the caudal extremity disappears. It is possible to distinguish the male and female organs from each other. The cloacal aperture in divided into two parts. The cartilaginous arches on the dorsal region of the spine close. The points of ossification for the occipital, sphenoid, lachrymal, nasal, squamous portion of temporal and ischium appear, as well as the orbital
centre of the superior maxillary. The pons Varolii and fissure of Sylvius can be made out. The eyelids, the hair, and the nails begin to form. The mammary gland, the epiglottis, and prostate are beginning to develop. The union of the testicle with the canals of the Wolffian body takes place.

**Fourth Month.**—The closure of the cartilaginous arches of the spine is complete. Osseous points for the first sacral vertebra and os pubis appear. The ossification of the malleus and incus takes place. The corpus callosum, the membrana lamina spiralis, the cartilage of the Eustachian tube, and the tympanic ring are seen. Fat is first developed in the subcutaneous cellular tissue. The tonsils are seen, and the closure of the genital furrow and the formation of the scrotum and prepuce take place.

**Fifth Month.**—The two layers of the decidua begin to coalesce. Osseous nuclei of the axis and odontoid process, of the lateral points of the first sacral vertebra, of the median points of the second, and of the lateral masses of the ethmoid make their appearance. Ossification of the stapes and the petrous bone and ossification of the germs of the teeth take place. The germ of the permanent teeth and the organ of Corti appear. The eruption of hair on the head commences. The sudoriferous glands, Brunner’s glands, the follicles of the tonsil and base of the tongue, and the lymphatic glands appear at this period. The differentiation between the uterus and vagina becomes apparent.

**Sixth Month.**—The points of ossification for the anterior root of the transverse process of the seventh cervical vertebra, the lateral points of the second sacral vertebra, the median points of the third, the manubrium sterni and the os calcis appear. The sacro-vertebral angle forms. The cerebral hemispheres cover the cerebellum. The papille of the skin, the sebaceous glands, and Peyer’s patches make their appearance. The free border of the nail projects from the corium of the dermis. The walls of the uterus thicken.

**Seventh Month.**—The additional points of the first sacral vertebra, the lateral points of the third, the median point of the fourth, the first osseous point of the body of the sternum, and the osseous point for the australasus appear. Meckel’s cartilage disappears. The cerebral convolutions, the island of Reil, and the tuberula quadrigemina are apparent. The papillary membrane atrophies. The testicle passes into the vaginal process of the peritoneum.

**Eighth Month.**—Additional points for the second sacral vertebra, lateral points for the fourth and median points for the fifth sacral vertebrae, can be seen.

**Ninth Month.**—Additional points for the third sacral vertebra, lateral points for the fifth, osseous points for the middle turbinate bone, for the body and great cornu of the hyoid, for the second and third pieces of the body of the sternum, and for the lower end of the femur appear. Ossification of the bony lamina spiralis and axis of the cochlea takes place. The eyelids open, and the testicles are in the scrotum.
DESCRIPTIVE AND SURGICAL ANATOMY.

OSTEOLOGY—THE SKELETON.

THE entire skeleton in the adult consists of 200 distinct bones. These are—

In this enumeration the patellæ are included as separate bones, but the smaller sesamoid bones and the ossicula auditūs are not reckoned. The teeth belong to the tegumentary system.

These bones are divisible into four classes: *Long, Short, Flat, and Irregular.*

The *Long Bones* are found in the limbs, where they form a system of levers, which have to sustain the weight of the trunk and to confer the power of locomotion. A long bone consists of a shaft and two extremities. The *shaft* is a hollow cylinder, contracted and narrowed to afford greater space for the bellies of the muscles; the walls consist of dense, compact tissue of great thickness in the middle, but becoming thinner toward the extremities; the spongy tissue is scanty, and the bone is hollowed out in its interior to form the *medullary canal.* The *extremities* are generally somewhat expanded for greater convenience of mutual connection, for the purposes of articulation, and to afford a broad surface for muscular attachment. Here the bone is made up of spongy tissue with only a thin coating of compact substance. The long bones are not straight, but curved, the curve generally taking place in two directions, thus affording greater strength to the bone. The bones belonging to this class are the *clavicle, humerus, radius, ulna, femur, tibia, fibula, metacarpal and metatarsal* bones, and the *phalanges*.

**Short Bones.**—Where a part of the skeleton is intended for strength and compactness, and its motion is at the same time slight and limited, it is divided into a number of small pieces united together by ligaments, and the separate bones are short and compressed, such as the bones of the *carpus* and *tarsus.* These bones, in their structure, are spongy throughout, excepting at their surface, where there is a thin crust of compact substance. The *patellæ* also, together with the other sesamoid bones, are by some regarded as short bones.

**Flat Bones.**—Where the principal requirement is either extensive protection or the provision of broad surfaces for muscular attachment, we find the osseous structure expanded into broad, flat plates, as is seen in the bones of the skull and the shoulder-blade. These bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the cranial bones these layers of compact tissue are familiarly known as the *tables* of the
skull; the outer one is thick and tough; the inner one thinner, denser, and more brittle, and hence termed the vitreous table. The intervening cancellous tissue is called the diploe. The flat bones are: the occipital, parietal, frontal, nasal, lachrymal, vomer, scapula, os innominatum, sternum, ribs, and patella.

The Irregular or Mixed Bones are such as, from their peculiar form, cannot be grouped under either of the preceding heads. Their structure is similar to that of other bones, consisting of a layer of compact tissue externally, and of spongy cancellous tissue within. The irregular bones are: the vertebrae, sacrum, coccyx, temporal, sphenoid, ethmoid, malar, superior maxillary, inferior maxillary, palate, inferior turbinated, and hyoid.

Surfaces of Bones.—If the surface of any bone is examined, certain eminences and depressions are seen to which descriptive anatomists have given the following names.

These eminences and depressions are of two kinds: articular and non-articular. Well-marked examples of articular eminences are found in the heads of the humerus and femur and of articular depressions in the glenoid cavity of the scapula and the acetabulum. Non-articular eminences are designated according to their form. Thus, a broad, rough, uneven elevation is called a tuberosity; a small, rough prominence, a tubercle; a sharp, slender, pointed eminence, a spine; a narrow, rough elevation, running some way along the surface, a ridge or line.

The non-articular depressions are also of very variable form, and are described as fossae, grooves, furrows, fissures, notches, etc. These non-articular eminences and depressions serve to increase the extent of surface for the attachment of ligaments and muscles, and are usually well marked in proportion to the muscularity of the subject.

A prominent process projecting from the surface of a bone, which has never been separate from or movable upon is termed an apophysis (from ἀπόφυσις, an excrecence); but if such process is developed as a separate piece from the rest of the bone, to which it is afterward joined, it is termed an epiphysis (from ἐπίφυσις, an accretion). Diaphysis means main part of a bone or shaft of a long bone.

THE SPINE.

The Spine is a flexuous and flexible column formed of a series of bones called vertebrae (from vertere, to turn).

The Vertebrae are thirty-three in number, exclusive of those which form the skull, and have received the names cervical, dorsal, lumbar, sacral, and coccygeal, according to the position which they occupy; seven being found in the cervical region, twelve in the dorsal, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or the number may be diminished in one region, the deficiency being supplied by an additional vertebra in another. These observations do not apply to the cervical portion of the spine, the number of bones forming which is seldom increased or diminished.

The vertebrae in the upper three regions of the spine are separate throughout the whole of life; but those found in the sacral and coccygeal regions are in the adult firmly united, so as to form two bones—five entering into the formation of the upper bone or sacrum, and four into the terminal bone of the spine or coccyx.

General Characters of a Vertebra.

Each vertebra consists of two essential parts—an anterior solid segment or body, and a posterior segment or arch. The arch (neural) is formed of two pedicles and two laminae, supporting seven processes—viz. four articular, two transverse, and one spinous.

The bodies of the vertebrae are piled one upon the other, forming a strong pillar for the support of the cranium and trunk; the arches forming a hollow cylinder behind the bodies for the protection of the spinal cord. The different
vertebrae are connected together by means of the articular processes and the intervertebral cartilages; while the transverse and spinous processes serve as levers for the attachment of muscles which move the different parts of the spine. Lastly, between each pair of vertebrae apertures exist through which the spinal nerves pass from the cord. Each of these constituent parts must now be separately examined.

The Body or Centrum is the largest and most solid part of a vertebra. Above and below it is flattened; its upper and lower surfaces are rough for the attachment of the intervertebral fibro-cartilages, and present a rim around their circumference. In front, it is convex from side to side, concave from above downward. Behind, it is flat from above downward and slightly concave from side to side. Its anterior surface is perforated by a few small apertures, for the passage of nutrient vessels; whilst on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins from the body of the vertebra—the **vena basis vertebrae**.

The Pedicles project backward, one on each side, from the upper part of the body of the vertebra, at the line of junction of its posterior and lateral surfaces. The concavities above and below the pedicles are the *intervertebral notches*; they are four in number, two on each side, the inferior ones being generally the deeper. When the vertebrae are articulated the notches of each contiguous pair of bones form the intervertebral foramina, which communicate with the spinal canal and transmit the spinal nerves and blood-vessels.

The Laminae are two broad plates of bone which complete the vertebral arch behind, enclosing a foramen, the spinal foramen, which serves for the protection of the spinal cord; they are connected to the body by means of the pedicles. Their upper and lower borders are rough, for the attachment of the *ligamenta subflava*.

The Spinous Process projects backward from the junction of the two laminae, and serves for the attachment of muscles.

The Articular Processes, four in number, two on each side, spring from the junction of the pedicles with the laminae. The two superior project upward, their articular surfaces being directed more or less backward; the two inferior project downward, their articular surfaces looking more or less forward.¹

The Transverse Processes, two in number, project one at each side from the point where the articular processes join the pedicle. They also serve for the attachment of muscles.

**Character of the Cervical Vertebrae** (Fig. 109).

The Cervical Vertebrae are smaller than those in any other region of the spine, and may readily be distinguished from the foramen in the transverse process, which does not exist in the transverse process of either the dorsal or lumbar vertebra.

The Body is small, comparatively dense, and broader from side to side than from before backward. The anterior and posterior surfaces are flattened and of equal depth: the former is placed on a lower level than the latter, and its inferior border is prolonged downward, so as to overlap the upper and fore part of the vertebrae below. Its upper surface is concave transversely, and presents a projecting lip on each side; its lower surface is convex from side to side, concave from before backward, and presents laterally a shallow concavity which receives the corresponding projecting lip of the adjacent vertebra. The pedicles are directed obliquely outward, and the superior intervertebral notches are deeper, but narrower, than the inferior. The laminae are narrow, long, thinner above than below, and overlap each other, enclosing the spinal foramen, which is very large, and of a triangular form. The spinous processes are short, and bifid at the extremity to afford greater extent of surface for the attachment of muscles, the two divisions being often of unequal size. They increase in length from the

¹It may, perhaps, be as well to remind the reader that the direction of a surface is determined by that of a line drawn at right angles to it.
fourth to the seventh. The *articulare processae* are oblique: the superior are of an oval form, flattened, and directed backward and upward; the inferior forward and downward. The *transverse processae* are short, directed downward, outward, and forward, bifid at their extremity, and marked by a groove along their upper surface, which runs downward and outward from the superior intervertebral notch, and serves for the transmission of one of the cervical nerves. They are situated in front of the articular processae and on the outer side of the pedicles. The transverse processae are pierced at their base by a foramen, for the transmission of the vertebral artery, vein, and plexus of nerves. Each process is formed by two roots: the anterior root, sometimes called the *costal process*, arises from the side of the body, and is the homologue of the rib in the dorsal region of the spine; the posterior root springs from the junction of the pedicle with the lamina, and corresponds with the transverse process in the dorsal region. It is by the

![Diagram of a vertebral column showing articular and transverse processes.](image)

junction of the two that the foramen for the vertebral vessels is formed. The extremity of each of these roots forms the *anterior* and *posterior tuberclae* of the transverse processae.

The peculiar vertebrae in the cervical region are the first, or *Atlas*; the second, or *Axis*; and the seventh, or *Vertebra prominens*. The great modifications in the form of the atlas and axis are designed to admit of the nodding and rotatory movements of the head.

The *Atlas* (Fig. 110) is so named from supporting the globe of the head. The chief peculiarities of this bone are that it has neither body nor spinous process. The body is detached from the rest of the bone, and forms the odontoid process of the second vertebra; while the parts corresponding to the pedicles join in front to form the anterior arch. The atlas consists of an anterior arch, a posterior arch, and two lateral masses. The anterior arch forms about one-fifth of the bone; its anterior surface is convex, and presents about its centre a *tubercle*, for the attachment of the Longus colli muscle; posteriorly it is concave, and marked by a smooth, oval or circular facet, for articulation with the odontoid process of the axis. The upper and lower borders give attachment to the anterior occipito-atlantal and the anterior atlanto-axial ligaments, which connect it with the occipital bone above and the axis below. The *posterior* arch forms about two-fifths of the circumference of the bone; it terminates behind in a *tubercle*, which is the rudiment of a spinous process, and gives origin to the Rectus capitis posticus minor. The diminutive size of this process prevents any interference in the movements between it and the cranium. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior occipito-atlantal ligae-

1The anterior tubercle of the transverse process of the sixth cervical vertebra is of large size, and is sometimes known as "Chassaignac's" or the "carotid tubercle." It is in close relation with the carotid artery, which lies in front and a little external to it so that, as was first pointed out by Chassaignac, the vessel can with ease be compressed against it.
ment, while in front, immediately behind each superior articular process, is a groove, sometimes converted into a foramen by a delicate bony spiculum which arches backward from the posterior extremity of the superior articular process. These grooves represent the superior intervertebral notches, and are peculiar from being situated behind the articular processes, instead of in front of them, as in the other vertebrae. They serve for the transmission of the vertebral artery, which, ascending through the foramen in the transverse process, winds round the lateral mass in a direction backward and inward. They also transmit the suboccipital nerve. On the under surface of the posterior arch, in the same situation, are two other grooves, placed behind the lateral masses, and representing the inferior intervertebral notches of other vertebrae. They are much less marked than the superior. The lower border also gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The lateral masses are the most bulky and solid parts of the atlas, in order to support the weight of the head; they present two articulating processes above, and two below. The two superior

![Rudimentary spinous process.](image)

**Fig. 110.—First cervical vertebra, or atlas.**

are of large size, oval, concave, and approach each other in front, but diverge behind; they are directed upward, inward, and a little backward, forming a kind of cup for the condyles of the occipital bone, and are admirably adapted to the nodding movements of the head. Not unfrequently they are partially subdivided by a more or less deep indentation which encroaches upon each lateral margin. The inferior articular processes are circular in form, flattened or slightly concave, and directed downward and inward, articulating with the axis, and permitting the rotatory movements. Just below the inner margin of each superior articular surface is a small tubercle, for the attachment of the transverse ligament, which, stretching across the ring of the atlas, divides it into two unequal parts; the anterior or smaller segment receiving the odontoid process of the axis, the posterior allowing the transmission of the spinal cord and its membranes. This part of the spinal canal is of considerable size, to afford space for the spinal cord; and hence lateral displacement of the atlas may occur without compression of this structure. The transverse processes are of large size, project directly outward from the lateral masses, and serve for the attachment of special muscles which assist in rotating the head. They are long, not bifid, and perforated at their base by a canal for the vertebral artery, which is directed from below, upward and backward.

The Axis (Fig. 111) is so named from forming the pivot upon which the first vertebra, carrying the head, rotates. The most distinctive character of this bone is the strong, prominent process, tooth-like in form (hence the name odontoid), which rises perpendicularly from the upper surface of the body. The body is of a triangular form, deeper in front than behind, and prolonged downward anteriorly so as to overlap the upper and fore part of the adjacent vertebra. It presents in front a median longitudinal ridge, separating two lateral depressions for the attach-
ment of the Longus colli muscle of either side. The odontoid process presents two articulating surfaces: one in front, of an oval form, for articulation with the atlas; another behind, for the transverse ligament—the latter frequently encroaching on the sides of the process. The apex is pointed, and gives attachment to one fasciculus of the odontoid ligament (ligamentum suspensorium). Below the apex the process is somewhat enlarged, and presents on either side a rough impression for the attachment of the lateral fasciculi of the odontoid or check ligaments, which connect it to the occipital bone; the base of the process, where it is attached to the body, is constricted, so as to prevent displacement from the transverse ligament, which binds it in this situation to the anterior arch of the atlas. Sometimes, however, this process does become displaced, especially in children, in whom the ligaments are more relaxed: instant death is the result of this accident. The pedicles are broad and strong, especially their anterior extremities, which coalesce with the sides of the body and the root of the odontoid process. The laminae are thick and strong, and the spinal foramen large, but smaller than that of the atlas. The transverse processes are very small, not bifid, and perforated by the vertebral foramen, or foramen for the vertebral artery, which is directed obliquely upward and outward. The superior articular surfaces are round, slightly convex, directed upward and outward, and are peculiar in being supported on the body, pedicles, and transverse processes. The inferior articular surfaces have the same direction as those of the other cervical vertebrae. The superior intervertebral notches are very shallow, and lie behind the articular processes; the inferior in front of them, as in the other cervical vertebrae. The spinous process is of large size, very strong, deeply channelled on its under surface, and presents a bifid, tubercular extremity for the attachment of muscles which serve to rotate the head upon the spine.

Seventh Cervical (Fig. 112).—The most distinctive character of this vertebra is
the existence of a very long and prominent spinous process; hence the name "vertebra prominens." This process is thick, nearly horizontal in direction, not bifurcated, and has attached to it the ligamentum nuchae. The transverse process is usually of large size, especially its posterior root; its upper surface has usually a shallow groove, and it seldom presents more than a trace of bifurcation at its extremity. The vertebral foramen is sometimes as large as in the other cervical vertebrae, but is usually smaller on one or both sides, and sometimes wanting. On the left side it occasionally gives passage to the vertebral artery; more frequently the vertebral vein traverses it on both sides; but the usual arrangement is for both artery and vein to pass in front of the transverse process, and not through the foramen.

Characters of the Dorsal Vertebrae.

The Dorsal Vertebrae are intermediate in size between those in the cervical and those in the lumbar region, and increase in size from above downward, the upper vertebrae in this segment of the spine being much smaller than those in the lower part of the region. The dorsal vertebrae may be at once recognized by the presence on the sides of the body of one or more facets or half-facets for the heads of the ribs.

The bodies of the dorsal vertebrae resemble those in the cervical and lumbar regions at the respective ends of this portion of the spine; but in the middle of the dorsal region their form is very characteristic, being heart-shaped, and as broad in the antero-posterior as in the lateral direction. They are thicker behind than in front, flat above and below, convex and prominent in front, deeply concave behind, slightly constricted in front and at the sides, and marked on each side, near the root of the pedicle, by two demi-facets, one above, the other below. These are covered with cartilage in the recent state, and, when articulated with the adjoining vertebrae, form, with the intervening fibro-cartilage, oval surfaces for the reception of the heads of the corresponding ribs. The pedicles are directed backward, and the inferior intervertebral notches are of large size, and deeper than in any other region of the spine. The laminae are broad, thick, and imbricated—that is to say, overlapping one another like tiles on a roof. The spinal foramen is small, and of a circular form. The spinous processes are long, triangular in form (bayonet-shaped), directed obliquely downward, and terminate in a tubercular extremity. They overlap one another from the fifth to the eighth, but are less
oblique in direction above and below. The articular processes are flat, nearly vertical in direction, and project from the upper and lower part of the pedicles;
LUMBAR VERTEBRAE.

151

The purpose of more closely connecting the segments of this portion of the spine or for muscular and ligamentous attachment. (See below, twelfth dorsal vertebra.)

The peculiar dorsal vertebrae are the first, ninth, tenth, eleventh, and twelfth (Fig. 114).

The First Dorsal Vertebra presents, on each side of the body, a single entire articular facet for the head of the first rib and a half facet for the upper half of the second. The upper surface of the body is like that of a cervical vertebra, being broad transversely, concave, and lipped on each side. The articular surfaces are oblique, and the spinous process thick, long, and almost horizontal.

The Ninth Dorsal has no demi-facet below. In some subjects, however, the ninth has two demi-facets on each side, then the tenth has a demi-facet at the upper part: none below.

The Tenth Dorsal has (except in the cases just mentioned) an entire articular facet on each side above, which is partly placed on the outer surface of the pedicle. It has no demi-facet below.

In the Eleventh Dorsal the body approaches in its form and size to the lumbar. The articular facets for the heads of the ribs, one on each side, are of large size, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the dorsal region. The spinous process is short, nearly horizontal in direction, and presents a slight tendency to bifurcation at its extremity. The transverse processes are very short, tubercular at their extremities, and have no articular facets for the tubercles of the ribs.

The Twelfth Dorsal has the same general characters as the eleventh, but may be distinguished from it by the inferior articular processes being convex and turned outward, like those of the lumbar vertebrae; by the general form of the body, laminae, and spinous process, approaching to that of the lumbar vertebrae; and by the transverse processes being shorter, and marked by three elevations, the superior, inferior, and external tubercles, which correspond to the mammillary, accessory, and transverse processes of the lumbar vertebrae. Traces of similar elevations are usually to be found upon the other dorsal vertebrae (vide ut supra).

Characters of the Lumbar Vertebrae.

The Lumbar Vertebrae (Fig. 115) are the largest segments of the vertebral column, and can at once be distinguished by the absence of the foramen in the transverse process, the characteristic point of the cervical vertebrae, and by the absence of any articulating facet on the side of the body, the distinguishing mark of the dorsal vertebrae.

The body is large, and has a greater diameter from side to side than from before backward, slightly thicker in front than behind, flattened or slightly concave above and below, concave behind, and deeply constricted in front and at the sides,
presenting prominent margins, which afford a broad basis for the support of the superincumbent weight. The pedicles are very strong, directed backward from the upper part of the bodies; consequently, the inferior intervertebral notches are of considerable depth. The laminae are broad, short, and strong, and the spinal foramen triangular, larger than in the dorsal, smaller than in the cervical, region. The spinous processes are thick and broad, somewhat quadrilateral, horizontal in direction, thicker below than above, and terminating by a rough, uneven border. The superior articular processes are concave, and look backward and inward; the inferior, convex, look forward and outward; the former are separated by a much wider interval than the latter, embracing the lower articulating processes of the vertebra above. The transverse processes are long, slender, directed transversely outward in the upper three lumbar vertebrae, slanting a little upward in the lower two. They are situated in front of the articular processes, instead of behind them as in the dorsal vertebrae, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the twelfth dorsal vertebra, the superior ones become connected in this region with the back part of the superior articular processes, and have received the name of mammillary processes; the inferior are represented by a small process pointing downward, situated at the back part of the base of the transverse process, and called the accessory processes: these are the true transverse processes, which are rudimental in this region of the spine; the external ones are the so-called transverse processes, the homologue of the rib, and hence sometimes called costal processes. Although in man these are comparatively small, in some animals they attain considerable size, and serve to lock the vertebrae more closely together.

The Fifth Lumbar vertebra is characterized by having the body much thicker in front than behind, which accords with the prominence of the sacro-vertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articulating processes; and by the greater size and thickness of its transverse processes.

Structure of the Vertebrae.—The structure of a vertebra differs in different parts. The body is composed of light, spongy, cancellous tissue, having a thin coating of compact tissue on its external surface perforated by numerous orifices, some of large size, for the passage of vessels; its interior is traversed by one or two large canals, for the reception of veins, which converge toward a single large, irregular aperture or several small apertures at the posterior part of the body of each bone. The arch and processes projecting from it have, on the contrary, an exceedingly thick covering of compact tissue.

Development.—Each vertebra is formed of four primary cartilaginous portions (Fig. 116), one for each lamina and its processes, and two for the body. Ossification commences in the laminae about the sixth week of foetal life, in the situation where the transverse processes afterward project, the ossific granules shooting backward to the spine, forward into the pedicles, and outward into the transverse and articular processes. Ossification in the body commences in the middle of the cartilage about the eighth week by two closely approximated centres, which speedily coalesce to form one central ossific point. According to some authors, ossification commences in the laminae only in the upper vertebrae—i. e. in the cervical and upper dorsal. The first ossific points in the lower vertebrae are those which are to form the body, the osseous centres for the laminae appearing at a subsequent period. At birth these three pieces are perfectly separate. During the first year the laminae become united behind by a portion of cartilage in which the spinous process is ultimately formed, and thus the arch is completed. About the third year the body is joined to the arch on each side, in such a manner that the body is formed from the three original centres of ossification, the amount contributed by the pedicles increasing in extent from below upward. Thus the bodies of the sacral vertebrae are formed almost entirely from the central nuclei; the bodies of the lumbar are formed laterally and behind by the pedicles; in the dorsal region the pedicles advance as far forward as the articular depressions for the head of the
ribs, forming these cavities of reception; and in the neck the lateral portions of the bodies are formed entirely by the advance of the pedicles. Before puberty no other changes occur, excepting a gradual increase in the growth of these primary centres; the upper and under surfaces of the bodies and the ends of the transverse and spinous processes being tipped with cartilage, in which ossific granules are not as yet deposited. At sixteen years (Fig. 118), four secondary centres appear, one for the tip of each transverse process, and two (sometimes united into one) for the end of the spinous process. At twenty-one years (Fig. 117), a thin circular epiphyseal plate of bone is formed in the layer of cartilage situated on the upper and under surfaces of the body, the former being the thicker of the two. All these become joined, and the bone is completely formed between the twenty-fifth and thirtieth year of life.

Exceptions to this mode of development occur in the first, second, and seventh cervical, and in the vertebrae of the lumbar region.

The Atlas (Fig. 119).—The number of centres of ossification of the atlas is very variable. It may be developed from two, three, four, or five centres. The most frequent arrangement is by three centres. Two of these are destined for the two lateral or neural masses, the ossification of which commences about the seventh week near the articular processes, and extend backward; these portions of bone are separated from one another behind, at birth, by a narrow interval filled in with cartilage. Between the second and third years they unite either directly or through the medium of a separate centre developed in the cartilage in the middle line. The anterior arch, at birth, is altogether cartilaginous, and in this a separate nucleus appears about the end of the first year after birth, and, extending laterally, joins the neural processes in front of the pedicles. Sometimes there are two nuclei developed in the cartilage, one on either side of the median line, which join to form a single mass. And occasionally there is no separate centre, but the
anterior arch is formed by the gradual extension forward and ultimate junction of the two neural processes.

The Axis (Fig. 120) is developed by six centres. The body and arch of this bone are formed in the same manner as the corresponding parts in the other vertebrae: one centre (or two, which speedily coalesce) for the lower part of the body, and one for each lamina. The odontoid process consists originally of an extension upward of the cartilaginous mass in which the lower part of the body is formed. At about the sixth month of foetal life two osseous nuclei make their appearance in the base of this process; they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval between the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage, the base of the process being separated from the body by a cartilaginous interval, which gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age. Finally, as Humphry has demonstrated, the apex of the odontoid process has a separate nucleus, which appears in the second year and joins about the twelfth year. In addition to these there is a secondary centre for a thin epiphysial plate on the under surface of the body of the bone.

The Seventh Cervical.—The anterior or costal part of the transverse process of the seventh cervical is developed from a separate osseous centre at about the sixth month of foetal life, and joins the body and posterior division of the transverse process between the fifth and sixth years. Sometimes this process continues as a separate piece, and, becoming lengthened outward, constitutes what is known as a cervical rib.

The Lumbar Vertebrae (Fig. 121) have two additional centres (besides those peculiar to the vertebrae generally) for the mammillary tubercles, which project from the back part of the superior articular processes. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain permanently unconnected with the remaining portion of the bone, thus forming a lumbar rib—a peculiarity which is rarely met with.

Progress of Ossification in the Spine generally.—Ossification of the laminae of the vertebrae commences at the upper part of the spine, and proceeds gradually downward. Ossification of the bodies, on the other hand, commences a little below the centre of the spinal column (about the ninth or tenth dorsal vertebra), and extends both upward and downward. Although, however, the ossific nuclei make their first appearance in the lower dorsal vertebra, the lumbar and first sacral are those in which these nuclei are largest at birth.

Attachment of Muscles.—To the Atlas are attached nine pairs: the Longus colli, Rectus capitis anticus minor, Rectus lateralis, Obliquus capitis superior and inferior, Splenius colli, Levator anguli scapulae, First Intertransversae, and Rectus capitis posticus minor.

To the Axis are attached eleven pairs: the Longus colli, Levator anguli scapulae, Splenius colli, Semispinalis capitis, orius medius, Transversalis colli, Intertransversales, Obliquus capitis inferior, Rectus capitis posticus major, Semispinalis colli, Multifidus spine, Interspinales.

To the remaining vertebrae, generally, are attached thirty-five pairs and a single muscle: anteriorly, the Rectus capitis anticus major, Longus colli, Semispinalis capitis medius and posticus, Psoas magnus and parvas, Quadratus lumborum, Diaphragm, Obliquus abdominis externus, and Transversalis abdominis—posteriorly, the Trapezius, Latissimus dorsi, Levator anguli scapulae, Rhomboides major and minor, Serratus posterior superior and inferior, Splenius, Erector spinae, Ilio-costalis, Longissimus dorsi, Spinalis dorsi, Cervicals ascendens, Transversalis colli, Tracheo-mastoid, Complexus, Biventer cervicis, Semispinalis dorsi and colli, Multifidus spine, Rotatores spine, Interspinales, Supraspinales, Intertransversales, Levatores costarum.

Sacral and Coccygeal Vertebrae.

The Sacral and Coccygeal Vertebrae consist, at an early period of life, of nine separate pieces, which are united in the adult so as to form two bones, five entering into the formation of the sacrum, four into that of the coccyx. Occasionally, the coccyx consists of five bones.¹

The Sacrum (sacer, sacred) is a large, triangular bone (Fig. 122), situated at the lower part of the vertebral column, and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two innominate bones; its upper part or base articulating with the last lumbar vertebrae, its apex with the coccyx. The sacrum is curved upon itself, and placed very obliquely, its upper extremity projecting forward, and forming, with the last lumbar vertebra, a very prominent angle, called the promontory or sacro-vertebral angle; whilst its central part is directed backward, so as to give increased capacity to the pelvic cavity. It presents for examination an anterior and posterior surface, two lateral surfaces, a base, an apex, and a central canal.

The Anterior Surface is concave from above downward, and slightly so from side to side. In the middle are seen four transverse ridges, indicating the original division of the bone into five separate pieces. The portions of bone intervening between the ridges correspond to the bodies of the vertebrae. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish in size from above downward, are flattened from before backward, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At each end of the ridges above mentioned are seen the anterior sacral foramina, analogous to the intervertebral foramina.

¹ Sir George Humphry describes this as the usual composition of the coccyx.—On the Skeleton, p. 456.
four in number on each side, somewhat rounded in form, diminishing in size from above downward, and directed outward and forward; they transmit the anterior branches of the sacral nerves. External to these foramina is the lateral mass, consisting at an early period of life of separate segments; these become blended, in the adult, with the bodies, with each other, and with the posterior transverse processes. Each lateral mass is traversed by four broad, shallow grooves, which lodge the anterior sacral nerves as they pass outward, the grooves being separated by prominent ridges of bone, which give attachment to the slips of the Pyriformis muscle.

If a vertical section is made through the centre of the bone (Fig. 123), the bodies are seen to be united at their circumference by bone, a wide interval being left centrally, which, in the recent state, is filled by intervertebral substance. In some bones this union is more complete between the lower segments than between the upper ones.

The Posterior Surface (Fig. 124) is convex and much narrower than the anterior. In the middle line are three or four tubercles, which represent the rudimentary spinous processes of the sacral vertebrae. Of these tubercles, the first is usually prominent, and perfectly distinct from the rest; the second and third are either separate or united into a tubercular ridge, which diminishes in size from above downward; the fourth usually, and the fifth always, remaining undeveloped. External to the spinous processes on each side are the laminae, broad and well marked in the first three pieces; sometimes the fourth, and generally the fifth, being undeveloped: in this situation the lower end of the sacral canal is exposed, and is liable to be opened in the sloughing of bed-soles. External to the laminae is a linear series of indistinct tubercles representing the articular processes; the upper pair are large, well developed, and correspond in shape and direction to the superior articulating processes of a lumbar vertebra; the second and third are small; the fourth and fifth (usually blended together) are situated on each side of the sacral canal: they are called the sacral cornua, and articulate with the cornua of the coccyx. External to the articular processes are the four posterior sacral foramina; they are smaller in size and less regular in form than the anterior, and transmit the posterior branches of the sacral nerves. On the outer side of the posterior sacral foramina is a series of tubercles, the rudimentary transverse processes of the sacral vertebrae. The first pair of transverse tubercles are large, very distinct, and correspond with each superior lateral angle of the bone; the second, small in size, enter into the formation of the sacro-iliac articulation; the third give attachment to the oblique fasciculi of the posterior sacro-iliac ligaments; and the fourth and fifth to the great sacro-scatic ligaments. The interspace between the spinous and transverse processes on the back of the sacrum presents a wide, shallow concavity, called the sacral groove; it is continuous above with the vertebral groove, and lodges the origin of the Erector spinae.
The Lateral Surface, broad above, becomes narrowed into a thin edge below. Its upper half presents in front a broad, ear-shaped surface for articulation with the ilium. This is called the auricular surface, and in the fresh state is coated with fibro-cartilage. It is bounded posteriorly by deep and uneven impressions, for the attachment of the posterior sacro-iliac ligaments. The lower half is thin and sharp, and ends in a prominence, the inferior lateral angle: the border gives attachment to the greater and lesser sacro-sciatic ligaments, and to some fibres of the Gluteus maximus; below the angle is a deep notch, which is converted into a foramen by the transverse process of the upper piece of the coccyx, and transmits the anterior division of the fifth sacral nerve.

The Base of the sacrum, which is broad and expanded, is directed upward and forward. In the middle is seen a large oval articular surface, which is connected with the under surface of the body of the last lumbar vertebra by a fibre-cartilaginous disk. It is bounded behind by the large, triangular orifice of the sacral canal. The orifice is formed behind by the lamina and spinous process of the first sacral vertebra: the superior articular processes project from it on each side; they are oval, concave, directed backward and inward, like the superior articular processes of a lumbar vertebra: and in front of each articular process is an intervertebral notch, which forms the lower half of the last intervertebral foramen. Lastly, on each side of the large oval articular surface is a broad and flat triangular surface of bone, which extends outward, supports the Psoas magnus muscle and lumbo-sacral cord, and is continuous on each side with the iliac fossa. This is called the ala of the sacrum, and gives attachment to a few of the fibres of the Iliacus muscle.

The Apex, directed downward and forward, presents a small, oval, concave surface for articulation with the coccyx.

The Spinal Canal runs throughout the greater part of the bone; it is large
and triangular in form above, small and flattened, from before backward, below. In this situation its posterior wall is incomplete, from the non-development of the laminae and spinous processes. It lodges the sacral nerves, and is perforated by the anterior and posterior sacral foramina, through which these pass out.

Structure.—It consists of much loose, spongy tissue within, invested externally by a thin layer of compact tissue.

Differences in the Sacrum of the Male and Female.—The sacrum in the female is usually wider than in the male; the lower half forms a greater angle with the upper, the upper half of the bone being nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backward, which increases the size of the pelvic cavity; but the sacro-vertebral angle projects less. In the male the curvature is more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Peculiarities of the Sacrum.—This bone, in some cases, consists of six pieces; occasionally, the number is reduced to four. Sometimes the bodies of the first and second segments are not joined or the laminae and spinous processes have not coalesced. Occasionally the upper pair of transverse tubercles are not joined to the rest of the bone on one or both sides; and, lastly, the sacral canal may be open for nearly the lower half of the bone, in consequence of the imperfect development of the laminae and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature. From the examination of a large number of skeletons it would appear that in one set of cases the anterior surface of this bone was nearly straight, the curvature, which was very slight, affecting only its lower end. In another set of cases the bone was curved throughout its whole length, but especially toward its middle. In a third set the degree of curvature was less marked, and affected especially the lower third of the bone.

Development (Fig. 125).—The sacrum, formed by the union of five vertebrae, has thirty-five centres of ossification.

The bodies of the sacral vertebrae have each three ossific centres: one for the central part, and one for the epiphysial plates on its upper and under surface. Occasionally the primary centres for the bodies of the first and second piece of the sacrum are double.

The arch of each sacral vertebra is developed by two centres, one for each lamina. These unite with each other behind, and subsequently join the body. The lateral masses have six additional centres, two for each of the first three vertebrae. These centres make their appearance above and to the outer side of the anterior sacral foramina (Fig. 125), and are developed into separate segments (Fig. 126); they are subsequently blended with each other, and with the bodies and transverse processes to form the lateral mass.

Lastly, each lateral surface of the sacrum is developed by two epiphysial plates (Fig. 127): one for the auricular surface, and one for the remaining part of the thin lateral edge of the bone.

---

---

**Fig. 125.—Development of the sacrum.**

**Fig. 126.**

**Fig. 127.**
Period of Development.—At about the eighth or ninth week of fetal life ossification of the central part of the bodies of the first three vertebrae commences, and at a somewhat later period that of the last two. Between the sixth and eighth months ossification of the laminae takes place; and at about the same period the characteristic osseous tubercles for the first three sacral vertebrae make their appearance. The period at which the arch becomes completed by the junction of the laminae with the bodies in front and with each other behind varies in different segments. The junction between the laminae and the bodies takes place first in the lower vertebra as early as the second year, but is not effected in the uppermost until the fifth or sixth year. About the sixteenth year the epiphyses for the upper and under surfaces of the bodies are formed, and between the eighteenth and twentieth years those for each lateral surface of the sacrum make their appearance. The bodies of the sacral vertebrae are, during early life, separated from each other by intervertebral disks. But about the eighteenth year the two lowest segments become joined together by ossification extending through the disk. This process gradually extends upward until all the segments become united, and the bone is completely formed from the twenty-fifth to the thirtieth year of life.

Articulations.—With four bones: the last lumbar vertebra, coccyx, and the two osa innominata.

Attachment of Muscles.—To eight pairs: in front, the Pyriformis and Coccygeus, and a portion of the Iliacus to the base of the bone; behind, the Gluteus maximus, Latissimus dorsi, Multifidus spineæ, and Erector spineæ, and sometimes the Extensor coccygis.

The Coccyx.

The Coccyx (κόκυξ, cuckoo), so called from having been compared to a cuckoo’s beak (Fig. 128), is usually formed of four small segments of bone, the most rudimentary parts of the vertebral column. In each of the first three segments may be traced a rudimentary body, articular and transverse processes; the last piece (sometimes the third) is a mere nodule of bone, without distinct processes. All the segments are destitute of pedicles, laminae, and spinous processes, and, consequently, of intervertebral foramina and spinal canal. The first segment is the largest: it resembles the lowermost sacral vertebra, and often exists as a separate piece; the last three, diminishing in size from above downward, are usually blended together so as to form a single bone. The gradual diminution in the size of the pieces gives this bone a triangular form, the base of the triangle joining the end of the sacrum. It presents for examination an anterior and posterior surface, two borders, a base, and an apex. The anterior surface is slightly concave, and marked with three transverse grooves, indicating the points of junction of the different pieces. It has attached to it the anterior sacro-coccygeal ligament and Levator ani muscle, and supports the lower end of the rectum. The posterior surface is convex, marked by transverse grooves similar to those on the anterior surface; and presents on each side a linear row of tubercles, the rudimentary articular processes of the coccygeal vertebrae. Of these, the superior pair are large, and are called the cornua of the coccyx; they project upward, and articulate with the cornua of the sacrum, the junction between these two bones completing the fifth posterior sacral foramen for the transmission of the posterior division of the fifth sacral nerve. The lateral borders are thin, and present a
series of small eminences, which represent the transverse processes of the coccygeal vertebrae. Of these, the first on each side is the largest, flattened from before backward, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the fifth anterior sacral foramen for the transmission of the anterior division of the fifth sacral nerve; the others diminish in size from above downward, and are often wanting. The borders of the coccyx are narrow, and give attachment on each side to the sacro-sciatic ligaments, to the Coccygeus muscle in front of the ligaments, and to the Gluteus maximus behind them. The base presents an oval surface for articulation with the sacrum. The apex is rounded, and has attached to it the tendon of the external Sphincter muscle. It is occasionally bifid, and sometimes deflected to one or other side.

Development.—The coccyx is developed by four centres, one for each piece. Occasionally one of the first three pieces of this bone is developed by two centres, placed side by side. The ossific nuclei make their appearance in the following order: in the first segment, at birth; in the second piece, at from five to ten years; in the third, from ten to fifteen years; in the fourth, from fifteen to twenty years. As age advances these various segments become united in the following order: the first two pieces join; then the third and fourth; and, lastly, the bone is completed by the union of the second and third. At a late period of life, especially in females, the coccyx often becomes joined to the end of the sacrum.

Articulation.—With the sacrum.

Attachment of Muscles.—To four pairs and one single muscle: on either side, the Coccygeus; behind, the Gluteus maximus and Extensor coccygis, when present; at the apex, the Sphincter ani; and in front, the Levator ani.

The Spine in General.

The Spinal Column, formed by the junction of the vertebrae, is situated in the median line, at the posterior part of the trunk; its average length is about two feet two or three inches, measuring along the curved anterior surface of the column. Of this length the cervical part measures about five, the dorsal about eleven, the lumbar about seven inches, and the sacrum and coccyx the remainder. The female spine is about one inch less than the male.
Viewed in front, it presents two pyramids joined together at their bases, the upper one being formed by all the vertebrae from the second cervical to the last lumbar, the lower one by the sacrum and coccyx. When examined more closely, the upper pyramid is seen to be formed of three smaller pyramids. The uppermost of these consists of the six lower cervical vertebrae, its apex being formed by the axis or second cervical, its base by the first dorsal. The second pyramid, which is inverted, is formed by the four upper dorsal vertebrae, the base being at the first dorsal, the smaller end at the fourth. The third pyramid commences at the fourth dorsal, and gradually increases in size to the fifth lumbar.

Viewed laterally (Fig. 129), the spinal column presents several curves, which correspond to the different regions of the column, and are called cervical, dorsal, lumbar, and pelvic. The cervical curve commences at the apex of the odontoid process, and terminates at the middle of the second dorsal vertebra; it is convex in front, and is the least marked of all the curves. The dorsal curve, which is concave forward, commences at the middle of the second, and terminates at the middle of the twelfth dorsal. Its most prominent point behind corresponds to the spine of the seventh dorsal vertebra. The lumbar curve commences at the middle of the last dorsal vertebra, and terminates at the sacro-vertebral angle. It is convex anteriorly; the convexity of the lower three vertebrae being much greater than that of the upper ones. The pelvic curve commences at the sacro-vertebral articulation and terminates at the point of the coccyx. It is concave anteriorly. The dorsal and pelvic curves are the primary curves, and begin to be formed at an early period of foetal life, and are due to the shape of the bodies of the vertebrae. The cervical and lumbar curves are compensatory or secondary, and are developed after birth in order to maintain the erect position. They are due mainly to the shape of the intervertebral disks.

The spine has also a slight lateral curvature, the convexity of which is directed toward the right side. This is most probably produced, as Bichat first explained, chiefly by muscular action, most persons using the right arm in preference to the left, especially in making long-continued efforts, when the body is curved to the right side. In support of this explanation it has been found by Bécqard that in one or two individuals who were left-handed the lateral curvature was directed to the left side.

The spinal column presents for examination an anterior, a posterior, and two lateral surfaces; a base, summit, and spinal canal.

The anterior surface presents the bodies of the vertebrae separated in the recent state by the intervertebral disks. The bodies are broad in the cervical region, narrow in the upper part of the dorsal, and broadest in the lumbar region. The whole of this surface is convex transversely, concave from above downward in the dorsal region, and convex in the same direction in the cervical and lumbar regions.

The posterior surface presents in the median line the spinous processes. These are short, horizontal, with bifid extremities, in the cervical region. In the dorsal region they are directed obliquely above, assume almost a vertical direction in the middle, and are horizontal below, as are also the spines of the lumbar vertebrae. They are separated by considerable intervals in the loins, by narrower intervals in the neck, and are closely approximated in the middle of the dorsal region. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the spine. On either side of the spinous processes, extending the whole length of the column, is the vertebral groove formed by the laminae in the cervical and lumbar regions, where it is shallow, and by the laminae and transverse processes in the dorsal region, where it is deep and broad. In the recent state these grooves lodge the deep muscles of the back. External to the vertebral grooves are the articular processes, and still more externally the transverse process. In the dorsal region the latter processes stand backward, on
a plane considerably posterior to the same processes in the cervical and lumbar regions. In the cervical region the transverse processes are placed in front of the articular processes, and on the outer side of the pedicles, between the intervertebral foramina. In the dorsal region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar they are placed also in front of the articular processes, but behind the intervertebral foramina.

The lateral surfaces are separated from the posterior by the articular processes in the cervical and lumbar regions, and by the transverse processes in the dorsal. These surfaces present in front the sides of the bodies of the vertebrae, marked in the dorsal region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the intervertebral notches, oval in shape, smallest in the cervical and upper part of the dorsal regions, and gradually increasing in size to the last lumbar. They are situated between the transverse processes in the neck, and in front of them in the back and loins, and transmit the spinal nerves.

The base of that portion of the vertebral column formed by the twenty-four movable vertebrae is formed by the under surface of the body of the fifth lumbar vertebra; and the summit by the upper surface of the atlas.

The vertebral or spinal canal follows the different curves of the spine; it is largest in those regions in which the spine enjoys the greatest freedom of movement, as in the neck and loins, where it is wide and triangular; and narrow and rounded in the back, where motion is more limited.

Surface Form.—The only part of the vertebral column which lies closely under the skin, and so directly influences surface form, is the apices of the spinous processes. These are always distinguishable at the bottom of a median furrow, which, more or less evident, runs down the mesial line of the back from the external occipital protuberance above to the middle of the sacrum below. In the neck the furrow is broad, and terminates below in a conspicuous projection, which is caused by the spinous process of the seventh cervical vertebra (vertebra prominens). Above this the spinous process of the sixth cervical vertebra may sometimes be seen; the other cervical spines are sunken, and are not visible, though the spine of the axis can be felt, and generally also the spines of the third, fourth, and fifth cervical vertebrae. In the dorsal region the furrow is shallow, and during stooping disappears, and then the spinous processes become more or less visible. The markings produced by these spines are small and close together. In the lumbar region the furrow is deep, and the situation of the lumbar spines is frequently indicated by little pits or depressions, especially if the muscles in the loins are well developed and the spine incurved. They are much larger and farther apart than in the dorsal region. In the sacral region the furrow is shallower, presenting a flattened area which terminates below at the most prominent part of the posterior surface of the sacrum, formed by the spinous process of the third sacral vertebra. At the bottom of the furrow may be felt the irregular posterior surface of the bone. Below this, in the deep groove leading to the anus, the coccyx may be felt. The only other portions of the vertebral column which can be felt from the surface are the transverse processes of three of the cervical vertebrae—viz. the first, the sixth, and the seventh. The transverse process of the atlas can be felt as a rounded nodule of bone just below and in front of the apex of the mastoid process, along the anterior border of the sterno-mastoid. The transverse process of the sixth cervical vertebra is of surgical importance. If deep pressure be made in the neck in the course of the carotid artery, opposite the criocid cartilage, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra can be felt. This has been named Chassaignac’s tubercle, and against it the carotid artery may be most conveniently compressed by the finger. The transverse process of the seventh cervical vertebra can also often be felt. Occasionally the anterior root, or costal process, is large and segmented off, forming a cervical rib.

Surgical Anatomy.—Occasionally the coalescence of the laminae is not completed, and consequently a cleft is left in the arches of the vertebra, through which a protrusion of the spinal membranes (dura mater and arachnoid), and sometimes of the spinal cord itself, takes place, constituting the disease known as spina bifida. This disease is most common in the lumbo-sacral region, on account of the fact, previously stated, that the closure of the arches takes place gradually from above downward; but it may occur in the dorsal or cervical region, or the arches throughout the whole length of the canal may remain unapproximated. In some rare cases, in consequence of the non-coalescence of the two primary centres from which the body is formed, a similar condition may occur in front of the canal, the bodies of the vertebrae being found cleft and the tumor projecting into the thorax, abdomen, or pelvis, between the lateral halves of the bodies affected.

The construction of the spinal column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, though per-
mitting of a very considerable range of movement as a whole, allows a sufficient degree of mobility without any material diminution of strength. The many joints of which the spine is composed, together with the very varied movements to which it is subjected, render it liable to sprains; but so closely are the individual vertebrae articulated that these sprains are rarely or ever severe, and any amount of violence sufficiently great to produce tearing of the ligaments would tend rather to cause a dislocation or fracture. The further safety of the column and its less liability to injury is provided for by its disposition in curves, instead of in one straight line. For it is an elastic column, and must first bend before it breaks: under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column than of a longer one that is equal to it in breadth and material. Again, the safety of the column is provided for by the interposition of the intervertebral disk between the bodies of the vertebrae, which act as admirable buffers in counteracting the effects of violent jars or shocks. Fracture-dislocation of the spine may be caused by direct or indirect violence, or by a combination of the two, as when a person, falling from a height, strikes against some prominence and is doubled over it. The fractures from indirect violence are the more common, and here the bodies of the vertebrae are compressed, whilst the arches are torn asunder; whilst in fractures from direct violence the arches are compressed and the bodies of the vertebrae separated from each other. It will therefore be seen that in both classes of injury the spinal marrow is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework, as Mr. Jacobson states, "being lodged in the centre of the column, it occupies neutral ground in respect to forces which might cause fracture. For it is a law in mechanics that when a beam, as of timber, is exposed to breakage and the force does not exceed the limits of the strength of the material, one division resists compression, another laceration of the particles, while the third, between the two, is in a negative condition." Applying this principle to the spine, it will be seen that, whether the fracture-dislocation be produced by direct violence or indirect, one segment, either the anterior or posterior, will be exposed to compression, the other to laceration, and the intermediate part, where the cord is situated, will be in a neutral state. When a fracture-dislocation is produced by indirect violence the displacement is almost always the same, the upper segment being driven forward on the lower, so that the cord is compressed between the body of the vertebra below and the arch of the vertebra above.

The parts of the spine most liable to be injured are (1) the dorsi-lumbar region, for this part is near the middle of the column, and there is therefore a greater amount of leverage, and moreover the portion above is comparatively fixed, and the vertebra which form it, though much smaller, have nevertheless to bear almost as great a weight as those below; (2) the cervico-dorsal region, because here the flexible cervical portion of the spine joins the more fixed dorsal region; and (3) the alto-axoid region, because it enjoys an extensive range of movement, and, being near the skull, is influenced by violence applied to the head. In fracture-dislocation it has been proposed to trephine the spine and remove portions of the laminae and spinous processes. The operation can only be of use when the paralysis is due to the pressure of bone or the effusion of blood, and not to cases, which are by far the most common, where the cord is crushed to a pulp. And even in those cases where the cord is compressed by bone the portion of displaced bone which presses on the cord is generally the body of the vertebra below, and is therefore inaccessible to operation. The operative proceeding is one of great severity, involving an extensive and deep wound and great risk of septic meningitis, and, as the advantages to be derived from it are exceedingly problematical and confined to a very few cases, it is not often resorted to. Trephining has also been resorted to in some cases of paraplegia due to Pott's disease of the spine. Here the paralysis is due to the pressure of inflammatory products, and where this is new scar-tissue, formed by the organization of granulation tissue, its removal has been attended with a very considerable amount of success.

THE SKULL.

The Skull, or superior expansion of the vertebral column, has been described as if composed of four vertebrae, the elementary parts of which are specially modified in form and size, and almost immovably connected, for the reception of the brain and special organs of the senses. These vertebrae are the occipital, parietal, frontal, and nasal. Descriptive anatomists, however, divide the skull into two parts, the Cranium and the Face. The Cranium (ξαρακέαν δος, a helmet) is composed of eight bones—viz. the occipital, two parietal, frontal, two temporal, sphenoid, and ethmoid. The Face is composed of fourteen bones—viz. the two nasal, two superior maxillary, two lachrymal, two malar, two palate, two inferior turbinated, vomer, and inferior maxillary. The ossiculi auditis, the teeth, and Wormian bones are not included in this enumeration.

1 Holmes's System of Surgery, vol. i. p. 529, 1883.
THE CRANIUM.

The Occipital Bone.

The Occipital Bone (ob, caput, against the head) is situated at the back part and base of the cranium, is trapezoid in form (Fig. 130), curved upon itself, and presents for examination two surfaces, four borders, and four angles.

The external surface is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum is a prominent tubercle, the external occipital protuberance, for the attachment of the Ligamentum nuchae; and, descending from it as far as the foramen, a vertical ridge, the external occipital crest. This tubercle and crest vary in prominence in different skulls. Passing outward from the occipital protuberance is a semicircular ridge on each side, the
superior curved line. Above this line there is often a second less distinctly marked ridge, called the highest curved line (linea suprema); to it the epianarial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge on each side, the inferior curved lines. The surface of the bone above the superior curved lines is rough and porous, and in the recent state is covered by the Occipito-frontalis muscle, while the ridges, as well as the surface of the bone between them, serve for the attachment of numerous muscles. The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipito-frontalis, and to the Sterno-cleido-mastoid to the extent shown in Fig. 130; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus capitis superior externally. The inferior curved line and the depressions below it afford insertion to the Rectus capitis posticus, major and minor.

The foramen magnum is a large, oval aperture, its long diameter extending from before backward. It transmits the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments. Its back part is wide for the transmission of the medulla, and the corresponding margin rough for the attachment of the dura mater enclosing it; the fore part is narrower, being encroached upon by the condyiles; it has projecting toward it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. On each side of the foramen magnum are the condyles, for articulation with the atlas; they are convex, oblong, or reniform in shape, and directed downward and outward; they converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each condyle is a rough tubercle for the attachment of the ligaments (cheek) which connect this bone with the odontoid process of the axis; whilst external to them is a rough tubercular prominence, the transverse or jugular process (the representative of the transverse process of a vertebra), channelled in front by a deep notch, which forms part of the jugular foramen or foramen lacerum posterius. The under surface of this process presents an eminence which represents the paramastoid process of some mammals. The eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipito-atlantal ligament; its upper or cerebral surface presents a deep groove which lodges part of the lateral sinus, whilst its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the anterior condyloid; it is directed downward, outward, and forward, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa, sometimes perforated at the bottom by a foramen, the posterior condyloid, for the transmission of a vein to the lateral sinus. In front of the foramen magnum is a strong quadrilateral plate of bone, the basilar process, wider behind than in front; its under surface, which is rough, presenting in the median line a tubercular ridge, the pharyngeal spine, for the attachment of the tendinous raphe and Superior constrictor of the pharynx; and on each side of it rough depressions for the attachment of the Rectus capitis anticus, major and minor.

The Internal or Cerebral Surface (Fig. 131) is deeply concave. The posterior or occipital part is divided by a crucial ridge into four fossae. The two superior fosse receive the occipital lobes of the cerebrum, and present slight eminences and depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and com-
paratively smooth; both are marked by slight grooves for the lodgment of arteries. At the point of meeting of the four divisions of the crucial ridge is an eminence, the internal occipital protuberance. It nearly corresponds to that on the outer surface, and is perforated by one or more large vascular foramina. From this eminence the superior division of the crucial ridge runs upward to the superior angle of the bone; it presents a deep groove for the superior longitudinal sinus, the margins of which give attachment to the falx cerebri. The inferior division, the internal occipital crest, runs to the posterior margin of the foramen magnum, on the edge of which it becomes gradually lost; this ridge, which is bifurcated below, serves for the attachment of the falx cerebelli. It is usually marked by a single groove, which commences at the back part of the foramen magnum and lodges the occipital sinus. Occasionally the groove is double where two sinuses exist. The transverse grooves pass outward to the lateral angles; they are deeply channelled, for the lodgment of the lateral sinuses, their prominent margins affording attachment to the tentorium cerebelli. At the point of meeting of these grooves is a depression, the torcular Herophili, placed a little to one or the other side of the internal occipital protuberance. More anteriorly is the foramen magnum, and on each side of it, but nearer its anterior than its posterior part, the

1 Usually one of the transverse grooves is deeper and broader than the other; occasionally, both grooves are of equal depth and breadth, or both equally indistinct. The broader of the two transverse grooves is nearly always continuous with the vertical groove for the superior longitudinal sinus.

2 The columns of blood coming in different directions were supposed to be pressed together at this point (torcular, a wine-press).
internal openings of the anterior condyloid foramina; the internal openings of the posterior condyloid foramina are a little external and posterior to them, protected by a small arch of bone. At this part of the internal surface there is a very deep groove in which the posterior condyloid foramen, when it exists, has its termination. This groove is continuous, in the complete skull, with the transverse groove on the posterior part of the bone, and lodges the end of the same sinus, the lateral. In front of the foramen magnum is the basilar process, presenting a shallow depression, the basilar groove, which slopes from behind, upward and forward, and supports the medulla oblongata and part of the pons Varolii, and on each side of the basilar process is a narrow channel, which, when united with a similar channel on the petrous portion of the temporal bone, forms a groove which lodges the inferior petrosal sinus.

Angles.—The superior angle is received into the interval between the posterior superior angles of the two parietal bones: it corresponds with that part of the skull in the fetus which is called the posterior fontanelle. The inferior angle is represented by the square-shaped surface of the basilar process. At an early period of life a layer of cartilage separates this part of the bone from the sphenoid, but in the adult the union between them is osseous. The lateral angles correspond to the outer ends of the transverse grooves, and are received into the interval between the posterior inferior angles of the parietal and the mastoid portion of the temporal.

Borders.—The superior border extends on each side from the superior to the lateral angle, is deeply serrated for articulation with the parietal bone, and forms, by this union, the lambdoid suture. The inferior border extends from the lateral to the inferior angle; its upper half is rough, and articulates with the mastoid portion of the temporal, forming the masto-occipital suture; the inferior half articulates with the petrous portion of the temporal, forming the petro-occipital suture; these two portions are separated from one another by the jugular process. In front of this process is a deep notch, which, with a similar one on the petrous portion of the temporal, forms the foramen lacerum posticus or jugular foramen. This notch is occasionally subdivided into two parts by a small process of bone, and it generally presents an aperture at its upper part, the internal opening of the posterior condyloid foramen.

Structure.—The occipital bone consists of two compact laminae, called the outer and inner tables, having between them the diploic tissue; this bone is especially thick at the ridges, protuberances, condyles, and internal part of the basilar process; whilst at the bottom of the fossæ, especially the inferior, it is thin, semitransparent, and destitute of diploë.

Development. (Fig. 132).—At birth the bone consists of four distinct parts: a tabular or expanded portion, which lies behind the foramen magnum; two condylar parts, which form the sides of the foramen; and a basilar part, which lies in front of the foramen. The number of nuclei for the tabular part vary. As a rule, there are four, but there may be only one (Blandin) or as many as eight (Meckel). They appear about the eighth week of foetal life, and soon unite to form a single piece, which is, however, fissured in the direction indicated in the plate. The basilar and two condyloid portions are each developed from a single nucleus, which appears a little later. The upper portion of the tabular surface—that is to say, the portion above the transverse fissure—is developed from membrane; the rest of the bone is developed from cartilage.
At about the fourth year the tabular and the two condyloid pieces join, and about the sixth year the bone consists of a single piece. At a later period, between the eighteenth and twenty-fifth years, the occipital and sphenoid become united, forming a single bone.

Articulations.—With six bones: two parietal, two temporal, sphenoid, and atlas.

Attachment of Muscles.—To twelve pairs: to the superior curved line are attached the Occipito-frontalis, Trapezius, and Sterno-cleido-mastoid. To the space between the curved lines, the Complexus,\(^1\) Splenius capitis, and Obliquus capitis superior; to the inferior curved line, and the space between it and the foramen magnum, the Rectus capitis posticus, major and minor; to the transverse process, the Rectus capitis lateralis; and to the basilar process, the Rectus capitis anticus, major and minor, and Superior constrictor of the pharynx.

The Parietal Bones.

The Parietal Bones (paries, a wall) form, by their union, the sides and roof of the skull. Each bone is of an irregular quadrilateral form, and presents for examination two surfaces, four borders, and four angles.

Surfaces.—The external surface (Fig. 133) is convex, smooth, and marked about its centre by an eminence called the parietal eminence, which indicates the point

\[\text{FIG. 133. — Left parietal bone. External surface.}\]

where ossification commenced. Crossing the middle of the bone in an arched direction are two well-marked curved lines or ridges, of which the lower is the more distinct and is termed the temporal ridge; it marks the upper attachment of the temporal muscle and follows a semicircular course across the bone. The upper ridge is less marked, and pursues a similar course across the bone, but about two-

\(^1\)To these the Biventer cervicis should be added, if it is regarded as a separate muscle.
fifths of an inch above the temporal ridge; it marks the attachment of the temporal fascia. Above these ridges the surface of the bone is rough and porous, and covered by the aponeurosis of the Occipito-frontalis; between them the bone is smoother and more polished than the rest; below them the bone forms part of the temporal fossa, and affords attachment to the temporal muscle. At the back part of the superior border, close to the sagittal suture, is a small foramen, the parietal foramen, which transmits a vein to the superior longitudinal sinus, and sometimes a small branch of the occipital artery. Its existence is not constant, and its size varies considerably.

The internal surface (Fig. 134), concave, presents eminences and depressions for lodging the convolutions of the cerebrum and numerous furrows for the ramifications of the meningeal arteries; the latter run upward and backward from the

![Diagram of the Left Parietal Bone Internal Surface]

**Fig. 134.** Left parietal bone. Internal surface.

anterior inferior angle and from the central and posterior part of the lower border of the bone. Along the upper margin is part of a shallow groove, which, when joined to the opposite parietal, forms a channel for the superior longitudinal sinus, the elevated edges of which afford attachment to the falx cerebri. Near the groove are seen several depressions, especially in the skulls of old persons; they lodge the Pacchionian bodies. The internal opening of the parietal foramen is also seen when that aperture exists.

**Borders.**—The superior, the longest and thickest, is dentated to articulate with its fellow of the opposite side, forming the sagittal suture. The inferior is divided into three parts: of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the great wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and overlapped by the squamous portion of the temporal; the posterior portion is thick and serrated for articulation with the mastoid portion of the temporal. The anterior border, deeply serrated, is bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone, forming the
coronal suture. The posterior border, deeply denticulated, articulates with the occipital, forming the lambdoid suture.

Angles.—The anterior superior angle, thin and pointed, corresponds with that portion of the skull which in the foetus is membranous and is called the anterior fontanelle. The anterior inferior angle is thin and lengthened, being received in the interval between the great wing of the sphenoid and the frontal. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior branch of the middle meningeal artery. The posterior superior angle corresponds with the junction of the sagittal and lambdoid sutures. In the foetus this part of the skull is membranous, and is called the posterior fontanelle. The posterior inferior angle articulates with the mastoid portion of the temporal bone, and generally presents on its inner surface a broad, shallow groove for lodging part of the lateral sinus.

Development.—The parietal bone is formed in membrane, being developed by one centre, which corresponds with the parietal eminence, and makes its first appearance about the seventh or eighth week of foetal life. Ossification gradually extends from the centre to the circumference of the bone: the angles are consequently the parts last formed, and it is in their situation that the fontanelles exist previous to the completion of the growth of the bone.

Articulations.—With five bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid.

Attachment of Muscles.—One only, the Temporal.

The Frontal Bone.

The Frontal Bone (frons, the forehead) resembles a cockle-shell in form, and consists of two portions—a vertical or frontal portion situated at the anterior part of the cranium, forming the forehead; and a horizontal or orbito-nasal portion which enters into the formation of the roof of the orbits and nasal fossae.
THE FRONTAL BONE.

Vertical Portion.—External Surface (Fig. 135).—In the median line, traversing the bone from the upper to the lower part, is occasionally seen a slightly-elevated ridge, and in young subjects a suture, which represents the line of union of the two lateral halves of which the bone consists at an early period of life; in the adult this suture is usually obliterated and the bone forms one piece; traces of the obliterated suture are, however, generally perceptible at the lower part. On either side of this ridge, a little below the centre of the bone, is a rounded eminence, the frontal eminence. These eminences vary in size in different individuals, and are occasionally unsymmetrical in the same subject. They are especially prominent in cases of well-marked cerebral development. The whole surface of the bone above this part is smooth, and covered by the aponeurosis of the Occipito-frontalis muscle. Below the frontal eminence, and separated from it by a slight groove, is the superciliary ridge, broad internally, where it is continuous with the nasal eminence, but less distinct as it arches outward. These ridges are caused by the projection outward of the frontal sinuses,¹ and give attachment to the Orbicularis palpebrarum and Corrugator supercilii. Between the two superciliary ridges is a smooth surface, the glabella or nasal eminence. Beneath the superciliary ridge is the supraorbital arch, a curved and prominent margin, which forms the upper boundary of the orbit, and separates the vertical from the horizontal portion of the bone. The outer part of the arch is sharp and prominent, affording to the eye, in that situation, considerable protection from injury; the inner part is less prominent. At the junction of the internal and middle third of this arch is a notch, sometimes converted into foramen by a bony process, and called the supraorbital notch or foramen. It transmits the supraorbital artery, vein, and nerve. A small aperture is seen in the upper part of the notch, which transmits a vein from the diploë to join the supraorbital vein. The supraorbital arch terminates externally in the external angular process and internally in the internal angular process. The external angular process is strong, prominent, and articulates with the malar bone; running upward and backward from it are two well-marked lines, which, commencing together from the external angular process, soon diverge from each other and run in a curved direction across the bone. The lower one, the temporal ridge, gives attachment to the Temporal muscle, the upper one to the temporal fascia. Beneath them is a slight concavity that forms the anterior part of the temporal fossa and gives origin to the Temporal muscle. The internal angular processes are less marked than the external, and articulate with the lachrymal bones. Between the internal angular processes is a rough, uneven interval, the nasal notch, which articulates in the middle line with the nasal bone, and on either side with the nasal process of the superior maxillary bone. From the concavity of this notch projects a process, the nasal process, which extends beneath the nasal bones and nasal processes of the superior maxillary bones and supports the bridge of the nose. On the under surface of this is a long pointed process, the nasal spine, and on either side a small grooved surface enters into the formation of the roof of the nasal fossa. The nasal spine forms part of the septum of the nose, articulating in front with the nasal bones and behind with the perpendicular plate of the ethmoid.

Internal Surface (Fig. 136).—Along the middle line is a vertical groove, the edges of which unite below to form a ridge, the frontal crest; the groove lodges the superior longitudinal sinus, whilst its margins afford attachment to the falx cerebri. The crest terminates below at a small notch which is converted into a foramen by articulation with the ethmoid. It is called the foramen cecum, and varies in size in different subjects: it is sometimes partially or completely impervious, lodges a process of the falx cerebri, and when open transmits a vein

¹Some confusion is occasioned to students commencing the study of anatomy by the name "sinuses" having been given to two perfectly different kinds of spaces connected with the skull. It may be as well, therefore, to state here, at the outset, that the "sinuses" in the interior of the cranium which produce the grooves on the inner surface of the bones are venous channels along which the blood runs in its passage back from the brain, while the "sinuses" external to the cranial cavity (the frontal, sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves which communicate with the nostrils, and contain air.
from the lining membrane of the nose to the superior longitudinal sinus. On either side of the groove the bone is deeply concave, presenting eminences and depressions for the convolutions of the brain, and numerous small furrows for lodging the ramifications of the anterior meningeal arteries. Several small, irregular fossae are also seen on either side of the groove, for the reception of the Pacchionian bodies.

**Horizontal Portion.**—*External Surface.*—This portion of the bone consists of two thin plates, which form the vault of the orbit, separated from one another by the ethmoidal notch. Each orbital vault consists of a smooth, concave, triangular plate of bone, marked at its anterior and external part (immediately beneath the external angular process) by a shallow depression, the lachrymal fossa, for lodging the lachrymal gland; and at its anterior and internal part by a depression (sometimes a small tubercle) for the attachment of the cartilaginous pulley of the Superior oblique muscle of the eye. The ethmoidal notch separates the two orbital plates; it is quadrilateral, and filled up, when the bones are united, by the cribiform plate of the ethmoid. The margins of this notch present several half-cells, which, when united with corresponding half-cells on the upper surface of the ethmoid, complete the ethmoidal cells; two grooves are also seen crossing these edges transversely; they are converted into canals by articulation with the ethmoid, and are called the *anterior and posterior ethmoidal canals*: they open on the inner wall of the orbit. The anterior one transmits the nasal nerve and anterior ethmoidal vessels, the posterior one the posterior ethmoidal vessels. In front of the ethmoidal notch, on either side of the nasal spine, are the openings of the frontal sinuses. These are two irregular cavities, which extend upward and outward, a variable distance, between the two tables of the skull, and are separated from one another by a thin, bony septum. They give rise to the
prominences above the supraorbital arches called the supr
ciliary ridges. In the child they are generally absent, and they become gradually developed as age advances. These cavities vary in size in different persons, are larger in men than in women, and are frequently of unequal size on the two sides, the right being 
commonly the larger. They are subdivided by a bony lamina, which is often displaced to one side. They are lined by mucous membrane, and communicate with the nose by the infundibulum, and occasionally with each other by apertures in their septum.

The internal surface of the horizontal portion presents the convex upper surfaces of the orbital plates, separated from each other in the middle line by the ethmoidal notch, and marked by eminences and depressions for the convolutions of the frontal lobes of the brain.

Borders.—The border of the vertical portion is thick, strongly serrated, bevelled at the expense of the internal table above, where it rests upon the parietal bones, and at the expense of the external table at each side, where it receives the lateral pressure of those bones; this border is continued below into a triangular rough surface which articulates with the great wing of the sphenoid. The border of the horizontal portion is thin, serrated, and articulates with the lesser wing of the sphenoid.

Structure.—The vertical portion and external angular processes are very thick, consisting of diploic tissue contained between two compact laminae. The horizontal portion is thin, translucent, and composed entirely of compact tissue; hence the facility with which instruments can penetrate the cranium through this part of the orbit.

Development (Fig. 137).—The frontal bone is formed in membrane, being developed by two centres, one for each lateral half, which make their appearance about the seventh or eighth week, above the orbital arches. From this point ossification extends, in a radiating manner, upward into the forehead and backward over the orbit. At birth the bone consists of two pieces, which afterward become united, along the middle line, by a suture which runs from the vertex to the root of the nose. This suture usually becomes obliterated within a few years after birth; but it occasionally remains throughout life. Occasionally secondary centres of ossification appear for the nasal spine—one on either side at the internal angular process where it articulates with the lachrymal bone; and sometimes there is one on either side at the lower end of the coronal suture. This latter centre sometimes remains ununited, and is known as the pterion oscicle, or it may join with the parietal, sphenoid, or temporal bone.

Articulations.—With twelve bones: two parietal, the sphenoid, the ethmoid, two nasal, two superior maxillary, two lacrymal, and two malar.

Attachment of Muscles.—To three pairs: the Corrugator supercilii, Orbicularis palpebrarum, and Temporal, on each side.

The Temporal Bones.

The Temporal Bones (tempus, time) are situated at the sides and base of the skull, and present for examination a squamous, mastoid, and petrous portion.

The squamous portion (squama, a scale), the anterior and upper part of the bone, is scale-like in form, and thin and translucent in texture (Fig. 138). Its outer surface is smooth, convex, and grooved at its back part for the deep temporal arteries; it affords attachment to the Temporal muscle and forms part of the temporal fossa. At its back part may be seen a curved ridge—part of the temporal.
ridge; it serves for the attachment of the temporal fascia, limits the origin of the Temporal muscle, and marks the boundary between the squamous and mastoid portions of the bone. Projecting from the lower part of the squamous portion is a long, arched process of bone, the *zygoma* or *zygomatic process*. This process is at first directed outward, its two surfaces looking upward and downward; it then appears as if twisted upon itself, and runs forward, its surfaces now looking inward and outward. The superior border of the process is long, thin, and sharp, and serves for the attachment of the temporal fascia. The inferior, short, thick, and arched, has attached to it some fibres of the Masseter muscle. Its outer surface is convex and subcutaneous; its inner is concave, and also affords attachment to the Masseter. The extremity, broad and deeply serrated, articulates with the malar bone. The zygomatic process is connected to the temporal bone by three divisions, called its *roots*—an anterior, middle, and posterior. The anterior, which is short, but broad and strong, is directed inward, to terminate in a rounded eminence, the *eminentia articularis*. This eminence forms the front boundary of the glenoid fossa, and in the recent state is covered with cartilage. The middle root (*post-glenoid process*) forms the posterior boundary of the mandibular portion of the glenoid fossa; while the posterior root, which is strongly marked, runs from the upper border of the zygoma, in an arched direction, upward and backward, forming the posterior part of the temporal ridge (*supramastoid crest*). At the junction of the anterior root with the zygoma is a projection, called the *tubercle*, for the attachment of the external lateral ligament of the lower jaw; and between the anterior and middle roots is an oval depression, forming part (mandibular) of the glenoid fossa (*γλασεριά*, a socket), for the reception of the condyle of the lower jaw. This fossa is bounded, in front, by the eminentia articularis; behind, by the tympanic plate and the auditory process; and is divided into two parts by a narrow slit, the *Glaserian fissure*. The anterior or mandibular part, formed by the squamous portion of the bone, is smooth, covered in the recent state with cartilage, and articulates with the condyle of the lower jaw. This part of the glenoid fossa is separated from the auditory process by the *post-glenoid process*, the representative of a prominent tubercle.

![Fig. 138.—Left temporal bone. Outer surface.](image-url)
which, in some of the mammalia, descends behind the condyle of the jaw, and prevents it being displaced backward during mastication (Humphry). The posterior part of the glenoid fossa, which lodges a portion of the parotid gland, is formed chiefly by the tympanic plate, a lamina of bone, which forms the anterior wall of the tympanum and external auditory meatus. This plate of bone terminates externally in the auditory process, above in the Glaserian fissure, and below forms a sharp edge, the vaginal process, which gives origin to some of the fibres of the Tensor palati muscle. The Glaserian fissure, which leads into the tympanum, lodges the processus gracilis of the malleus, and transmits the tympanic branch of the internal maxillary artery. The chorda tympani nerve passes through a separate canal, parallel to the Glaserian fissure (canal of Huguier), on the outer side of the Eustachian tube, in the retiring angle between the squamous and petrous portions of the temporal bone.¹

The internal surface of the squamous portion (Fig. 139) is concave, presents numerous eminences and depressions for the convolutions of the cerebrum, and two well-marked grooves for the branches of the middle meningeal artery.

Borders.—The superior border is thin, bevelled at the expense of the internal surface, so as to overlap the lower border of the parietal bone, forming the squamous suture. The anterior inferior border is thick, serrated, and bevelled, alternately at the expense of the inner and outer surfaces, for articulation with the great wing of the sphenoid.

The Mastoid Portion (μαστός, a nipple or teat) is situated at the posterior part of the bone; its outer surface is rough, and gives attachment to the Occipito-frontalis and Retractens aurem muscles. It is perforated by numerous foramina; one of these, of large size, situated at the posterior border of the bone, is termed the mastoid foramen; it transmits a vein to the lateral sinus and a small artery from the occipital to supply the dura mater. The position and size of this foramen

¹ This small fissure must not be confounded with the large canal which lies above the Eustachian tube and transmits the Tensor tympani muscle.

---

**Fig. 139.—Left temporal bone. Inner surface.**
are very variable. It is not always present; sometimes it is situated in the occipital bone or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the mastoid process, the size and form of which vary somewhat. This process serves for the attachment of the Sterno-mastoid, Splenius capitis, and Trachelo-mastoid muscles. On the inner side of the mastoid process is a deep groove, the digastric fossa, for the attachment of the Digastric muscle; and, running parallel with it, but more internal, the occipital groove, which lodges the occipital artery. The internal surface of the mastoid portion presents a deep, curved groove, the fossa sigmoida, which lodges part of the lateral sinus; and into it may be seen opening the mastoid foramen. A section of the mastoid process shows it to be hollowed out into a number of cellular spaces, communicating with each other, called the mastoid cells; they open by a single or double orifice into the back of the tympanum, are lined by a prolongation of its lining membrane, and probably form some secondary part of the organ of hearing. The spaces at the upper and front part of the bone near the opening into the tympanum are large and irregular, and contain air. They diminish in size toward the lower part of the bone, those situated at the apex of the mastoid process being quite small and usually containing marrow (Fig. 140).

The mastoid cells, like the other sinuses of the cranium, are not developed until after puberty; hence the prominence of this process in the adult.

In consequence of the communication which exists between the tympanum and mastoid cells, inflammation of the lining membrane of the former cavity may easily travel backward to that of the mastoid cells, leading to caries and necrosis of their walls and the risk of transference of the inflammation to the lateral sinus or encephalon.

Borders.—The superior border of the mastoid portion is broad and rough, its serrated edge sloping outward, for articulation with the posterior inferior angle of the parietal bone. The posterior border, also uneven and serrated, articulates with the inferior border of the occipital bone between its lateral angle and jugular process.

The Petrous Portion (πετρος, a stone), so named from its extreme density and hardness, is a pyramidal process of bone wedged in at the base of the skull between the sphenoid and occipital bones. Its direction from without is inward,
forward, and a little downward. It presents for examination a base, an apex, three surfaces, and three borders, and contains, in its interior, the essential parts of the organ of hearing. The base is applied against the internal surface of the squamous and mastoid portions, its upper half being concealed; but its lower half is exposed by the divergence of those two portions of the bone, which brings into view the oval expanded orifice of a canal leading into the tympanum, the meatus auditorius externus. This canal is situated in front of the mastoid process, and between the posterior and middle roots of the zygoma; its upper margin is smooth and rounded, but the greater part of its circumference is surrounded by a curved plate of bone, the auditory process, the free margin of which is thick and rough, for the attachment of the cartilage of the external ear.

The apex of the petrous portion, rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid and the basilar process of the occipital; it presents the anterior or internal orifice of the carotid canal, and forms the posterior and external boundary of the foramen lacerum medium.

The anterior surface of the petrous portion (Fig. 139) forms the posterior part of the middle fossa of the skull. This surface is continuous with the squamous portion, to which it is united by a suture, the temporal or petro-squamous suture, the remains of which are distinct even at a late period of life; it presents six points for examination: 1, an eminence near the centre, which indicates the situation of the superior semicircular canal; 2, on the outer side of this eminence a depression indicating the position of the tympanum; here the layer of bone which separates the tympanum from the cranial cavity is extremely thin, and is known as the tegmen tympani; 3, a shallow groove, sometimes double, leading outward and backward to an oblique opening, the hiatus Fallopii, for the passage of the petrosal branch of the Vidian nerve and the petrosal branch of the middle meningeal artery; 4, a smaller opening, occasionally seen external to the latter, for the passage of the smaller petrosal nerve; 5, near the apex of the bone, the termination of the carotid canal, the wall of which in this situation is deficient in front; 6, above this canal a shallow depression for the reception of the Gasserian ganglion.

The posterior surface forms the front part of the posterior fossa of the skull, and is continuous with the inner surface of the mastoid portion of the bone. It presents three points for examination: 1. About its centre, a large orifice, the meatus auditorius internus, whose size varies considerably; its margins are smooth and rounded, and it leads into a short canal, about four lines in length, which runs directly outward and is closed by a vertical plate, the lamina cribrosa, which is divided by a horizontal crest, the crista falciformis, into two unequal portions; the lower presenting three foramina or sets of foramina; one, just below the posterior part of the crest, consisting of a number of small openings for the nerves to the sacculus; a second, below and posterior to this, for the nerve to the posterior semicircular canal; and a third, in front and below the first, consisting of a number of small openings which terminate in the canalis centralis cochleae and transmit the nerve to the cochlea; the upper portion, that above the crista, presents behind a series of small openings for the passage of filaments to the vestibule and superior and external semicircular canal, and, in front, one large opening, the commencement of the aqueductus Fallopii, for the passage of the facial nerve. 2. Behind the meatus auditorius, a small slit, almost hidden by a thin plate of bone, leading to a canal, the aqueductus vestibuli, which transmits a small artery and vein and lodges a process of the dura mater. 3. In the interval between these two openings, but above them, an angular depression which lodges a process of the dura mater, and transmits a small vein into the cancellous tissue of the bone.

The inferior or basilar surface (Fig. 141) is rough and irregular, and forms part of the base of the skull. Passing from the apex to the base, this surface presents eleven points for examination: 1, a rough surface, quadrilateral in form, which
serves partly for the attachment of the Levator palati and Tensor tympani muscles; 2, the large, circular aperture of the carotid canal, which ascends at first vertically, and then, making a bend, runs horizontally forward and inward; it transmits the internal carotid artery and the carotid plexus; 3, the aqueductus cochleae, a small, triangular opening, lying on the inner side of the latter, close to the posterior border of the petrous portion; it transmits a vein from the cochlea which joins the internal jugular; 4, behind these openings a deep depression, the jugular fossa, which varies in depth and size in different skulls; it lodges the lateral sinus, and, with a similar depression on the margin of the jugular process of the occipital bone, forms the foramen lacerum posticus or jugular foramen; 5, a small foramen for the passage of Jacobson's nerve (the tympanic branch of the glosso-pharyngeal); this foramen is seen in front of the bony ridge dividing

the carotid canal from the jugular fossa; 6, a small foramen on the outer wall of the jugular fossa, for the entrance of the auricular branch of the pneumogastric (Arnold's) nerve; 7, behind the jugular fossa a smooth, square-shaped facet, the jugular surface; it is covered with cartilage in the recent state, and articulates with the jugular process of the occipital bone; 8, the vaginal process, a very broad, sheath-like plate of bone, which extends backward from the carotid canal and gives attachment to part of the Tensor palatii muscle; this plate divides behind into two laminae, the outer of which is continuous with the auditory process, the inner with the jugular process; between these laminae is the ninth point for examination, the styloid process, a long, sharp spine, about an inch in length: it is directed downward, forward, and inward, varies in size and shape, and sometimes consists of several pieces, united by cartilage; it affords attachment to three muscles, the Stylo-pharyngeus, Stylo-hyoides, and Stylo-glossus, and two ligaments, the stylo-hyoid and stylo-maxillary; 10, the stylo-mastoid foramen, a rather large orifice, placed between the styloid and mastoid processes: it is the termina-

FIG. 141.—Petrus portion. Inferior surface.
tion of the aqueductus Fallopii, and transmits the facial nerve and stylo-mastoid artery; 11. the auricular fissure, situated between the auditory and mastoid processes, for the exit of the auricular branch of the pneumogastric nerve.

Borders.—The superior, the longest, is grooved for the superior petrosal sinus, and has attached to it the tentorium cerebelli; at its inner extremity is a semilunar notch, upon which the fifth nerve lies. The posterior border is intermediate in length between the superior and the anterior. Its inner half is marked by a groove, which, when completed by its articulation with the occipital, forms the channel for the inferior petrosal sinus. Its outer half presents a deep excavation—the jugular fossa—which, with a similar notch on the occipital, forms the foramen lacerum posterior. A projecting eminence of bone occasionally stands out from the centre of the notch, and divides the foramen into two parts. The anterior border is divided into two parts—an outer joined to the squamous portion by a suture, the remains of which are distinct; an inner, free, articulating with the spinous process of the sphenoid. At the angle of junction of the petrous and squamous portions are seen two canals, separated from one another by a thin plate of bone, the processus cochleariformis; they both lead into the tympanum, the upper one transmitting the Tensor tympani muscle, the lower one the Eustachian tube.

Structure.—The squamous portion is like that of the other cranial bones; the mastoid portion, cellular; and the petrous portion, dense and hard.

Development (Fig. 142).—The temporal bone is developed by ten centres, exclusive of those for the internal ear and the ossicula—viz. one for the squamous portion including the zygoma, one for the tympanic plate, six for the petrous and mastoid parts, and two for the styloid process. Just before the close of foetal life the temporal bone consists of four parts: 1. The squamo-zygomatic, which is ossified in membrane from a single nucleus, which appears at its lower part about the second month. 2. The tympanic plate, an imperfect ring, which encloses the tympanic membrane. This is also ossified from a single centre, which appears rather later than that for the squamous portion. 3. The petro-mastoid, which is developed from six centres, which appear about the fifth or sixth month. Four of these are for the petrous portion, and are placed around the labyrinth, and two for the mastoid (Vrolik). According to Huxley, the centres are more numerous, and are disposed so as to form three portions: (1) including most of the labyrinth, with a part of the petrous and mastoid, he has named prootic; (2) the rest of the petrous, the opisthotic; and (3) the remainder of the mastoid, the epiotic. The petro-mastoid is ossified in cartilage. 4. The styloid process is also ossified in cartilage from two centres: one for the base, which appears before birth, and is termed the tympano-hyal; the other, comprising the rest of the process, is named the stylo-hyal, and does not appear until after birth. Shortly before birth the tympanic plate joins with the squamous. The petrous and mastoid join with the squamous during the first year, and the tympano-hyal portion of the styloid process about the same time. The stylo-hyal does not join the rest of the bone until after puberty, and in some skulls never becomes united. The subsequent changes in this bone are, that the tympanic plate extends outward, so as to form the meatus auditorius;
the glenoid fossa becomes deeper; and the mastoid part, which at an early period of life is quite flat, enlarges from the development of the cellular cavities in its interior.

Articulations.—With five bones—occipital, parietal, sphenoid, inferior maxillary, and malar.

Attachment of Muscles.—To fifteen: to the squamous portion, the Temporal; to the zygoma, the Masseter; to the mastoid portion, the Occipito-frontalis, Sterno-mastoid, Splenius capitis, Trachelo-mastoid, Digastricus, and Retrahrens aurenum; to the styloid process, the Stylo-pharyngeus, Stylo-hyoides, and Stylo-glossus; and to the petrous portion, the Levator palati, Tensor tympani, Tensor palatini, and Stapedius.

The Sphenoid Bone.

The Sphenoid Bone (αφην, a wedge) is situated at the anterior part of the base of the skull, articulating with all the other cranial bones, which it binds firmly and solidly together. In its form it somewhat resembles a bat with its wings extended; and is divided into a central portion or body, two greater and two lesser wings extending outward on each side of the body, and two processes—the pterygoid processes—which project from it below.

The body is of large size, cuboid in form, and hollowed out in its interior so as to form a mere shell of bone. It presents for examination four surfaces—a superior, an inferior, an anterior, and a posterior.

The Superior Surface (Fig. 143).—In front is seen a prominent spine, the ethmoidal spine, for articulation with the cribiform plate of the ethmoid; behind

FIG. 143.——Sphenoid bone. Superior surface.

this a smooth surface presenting, in the median line, a slight longitudinal eminence, with a depression on each side for lodging the olfactory tracts. This surface is bounded behind by a ridge, which forms the anterior border of a narrow, transverse groove, the optic groove; it lodges the optic commissure, and terminates on either side in the optic foramen, for the passage of the optic nerve and ophthalmic artery. Behind the optic groove is a small eminence, olive-like in shape, the olivary process; and still more posteriorly, a deep depression, the pituitary fossa, or sella turcica, which lodges the pituitary body. This fossa is perforated by numerous foramina, for the transmission of nutrient vessels into the substance of the bone. It is bounded in front by two small eminences, one on either side, called the middle clinoide processes (ζηληγ, a bed), which are sometimes connected by a spiculum of bone to the anterior clinoide processes, and behind by a square-
shaped plate of bone, the dorsum ephippii or dorsum sellae, terminating at each superior angle in a tubercle, the posterior clinoid processes, the size and form of which vary considerably in different individuals. These processes deepen the pituitary fossa, and serve for the attachment of prolongations from the tentorium cerebelli. The sides of the dorsum ephippii are notched for the passage of the sixth pair of nerves. and below present a sharp process, the petrosal process, which is joined to the apex of the petrous portion of the temporal bone, forming the inner boundary of the middle lacerated foramen. Behind this plate the bone presents a shallow depression, which slopes obliquely backward, and is continuous with the basilar groove of the occipital bone; it is called the clivus, and supports the upper part of the pons Varolii. On either side of the body is a broad groove, curved something like the italic letter f; it lodges the internal carotid artery and the cavernous sinus, and is called the carotid or cavernous groove. Along the outer margin of this groove, at its posterior part, is a ridge of bone in the angle between the body and greater wing, called the lingula. The posterior surface, quadrilateral in form, is joined to the basilar process of the occipital bone. During childhood these bones are separated by a layer of cartilage; but in after-life (between the eighteenth and twenty-fifth years) this becomes ossified, ossification commencing above and extending downward; and the two bones then form one piece. The anterior surface (Fig. 144) presents, in the middle line, a vertical ridge of bone, the ethmoidal crest, which articulates in front with the perpendicular plate of the ethmoid, forming part of the septum of the nose. On either side of it are irregular openings leading into the sphenoidal cells or sinuses. These are two large irregular cavities hollowed out of the interior of the body of the sphenoid bone, and separated from one another by a more or less complete perpendicular bony septum. Their form and size vary considerably; they are seldom symmetrical, and are often partially subdivided by irregular osseous laminae. Occasionally, they extend into the basilar process of the occipital nearly as far as the foramen magnum. The septum is seldom quite vertical, being commonly bent to one or the other side. These sinuses do not exist in children, but they increase in size as age advances. They are partially closed, in front and below, by two thin, curved plates of bone, the sphenoidal turbinated bones, leaving a round opening at their upper parts, by which they communicate with the upper and back part of the nose, and occasionally

1 In this figure, both the anterior and inferior surfaces of the body of the sphenoid bone are shown, the bone being held with the pterygoid processes almost horizontal.
with the posterior ethmoidal cells or sinuses. The lateral margins of this surface present a serrated edge, which articulates with the os planum of the ethmoid, completing the posterior ethmoidal cells; the lower margin, also rough and serrated, articulates with the orbital process of the palate bone, and the upper margin with the orbital plate of the frontal bone. The inferior surface presents, in the middle line, a triangular spine, the rostrum, which is continuous with the ethmoidal crest on the anterior surface and is received into a deep fissure between the alae of the vomer. On each side may be seen a projecting lamina of bone, which runs horizontally inward from near the base of the pterygoid process: these plates, termed the vaginal processes, articulate with the edges of the vomer. Close to the root of the pterygoid process is a groove, formed into a complete canal when articulated with the sphenoidal process of the palate bone; it is called the pterygo-palatine canal, and transmits the pterygo-palatine vessels and pharyngeal nerve.

The Greater Wings are two strong processes of bone which arise from the sides of the body, and are curved in a direction upward, outward, and backward, being prolonged behind into a sharp-pointed extremity, the spinous process of the sphenoid. Each wing presents three surfaces and a circumference. The superior or cerebral surface (Fig. 143) forms part of the middle fossa of the skull; it is deeply concave, and presents eminences and depressions for the convolutions of the brain. At its anterior and internal part is seen a circular aperture, the foramen rotundum, for the transmission of the second division of the fifth nerve. Behind and external to this is a large oval foramen, the foramen ovale, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small petrosal nerve. At the inner side of the foramen ovale a small aperture may occasionally be seen opposite the root of the pterygoid process; it is the foramen Vesalii, transmitting a small vein. Lastly, in the posterior angle, near to the spine of the sphenoid, is a short canal, sometimes double, the foramen spinosum; it transmits the middle meningeal artery. The external surface (Fig. 144) is convex, and divided by a transverse ridge, the pterygoid ridge, into two portions. The superior or larger, convex from above downward, concave from before backward, enters into the formation of the temporal fossa, and gives attachment to part of the Temporal muscle. The inferior portion, smaller in size and concave, enters into the formation of the zygomatic fossa, and affords attachment to the External pterygoid muscle. It presents, at its posterior part, a sharp-pointed eminence of bone, the spinous process, to which are connected the internal lateral ligament of the lower jaw and the Tensor palati muscle. The pterygoid ridge, dividing the temporal and zygomatic portions, gives attachment to part of the External pterygoid muscle. At its inner and anterior extremity is a triangular spine of bone which serves to increase the extent of origin of this muscle. The anterior or orbital surface, smooth and quadrilateral in form, assists in forming the outer wall of the orbit. It is bounded above by a serrated edge, for articulation with the frontal bone; below, by a rounded border which enters into the formation of the sphenomaxillary fissure. Internally, it presents a sharp border, which forms the lower boundary of the sphenoidal fissure, and is projecting from about its centre a little tubercle of bone, which gives origin to one head of the External rectus muscle of the eye; and at its upper part is a notch for the transmission of a branch of the lachrymal artery; externally it presents a serrated margin for articulation with the malar bone. One or two small foramina may occasionally be seen for the passage of branches of the deep temporal arteries; they are called the external orbital foramina. Circumference of the great wing (Fig. 143): commencing from behind, from the body of the sphenoid to the spine, the outer half of this margin is serrated, for articulation with the petrous portion of the temporal bone, whilst the inner half forms the anterior

1 The small petrosal nerve sometimes passes through a special foramen between the foramen ovale and foramen spinosum.

2 Sometimes called infratemporal crest.
boundary of the foramen lacerum medium, and presents the posterior aperture of the Vidian canal for the passage of the Vidian nerve and artery. In front of the spine the circumference of the great wing presents a serrated edge, bevelled at the expense of the inner table below and of the external above, which articulates with the squamous portion of the temporal bone. At the tip of the great wing a triangular portion is seen, bevelled at the expense of the internal surface, for articulation with the anterior inferior angle of the parietal bone. Internal to this is a broad, serrated surface, for articulation with the frontal bone: this surface is continuous internally with the sharp inner edge of the orbital plate, which assists in the formation of the sphenoidal fissure, and externally with the serrated margin for articulation with the malar bone.

The Lesser Wings (processes of Ingrassias) are two thin, triangular plates of bone which arise from the upper and lateral parts of the body of the sphenoid, and, projecting transversely outward, terminate in a sharp point (Fig. 143). The superior surface of each is smooth, flat, broader internally than externally, and supports part of the frontal lobe of the brain. The inferior surface forms the back part of the roof of the orbit and the upper boundary of the sphenoidal fissure or foramen lacerum anterius. This fissure is of a triangular form, and leads from the cavity of the cranium into the orbit; it is bounded internally by the body of the sphenoid—above, by the lesser wing; below, by the internal margin of the orbital surface of the great wing—and is converted into a foramen by the articulation of this bone with the frontal. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The anterior border of the lesser wing is serrated for articulation with the frontal bone; the posterior, smooth and rounded, is received into the fissure of Sylvius of the brain. The inner extremity of this border forms the anterior clinoid process. The lesser wing is connected to the side of the body by two roots, the upper thin and flat, the lower thicker, obliquely directed, and presenting on its outer side, near its junction with the body, a small tubercle, for the attachment of the common tendon of three of the muscles of the eye. Between the two roots is the optic foramen, for the transmission of the optic nerve and ophthalmic artery.

The Pterygoid Processes (πτέρυγων, a wing; εἶδος, likeness), one on each side, descend perpendicularly from the point where the body and greater wing unite (Fig. 145). Each process consists of an external and an internal plate, separated behind by an intervening notch—the pterygoid fossa; but joined partially in front. The external pterygoid plate is broad and thin, turned a little outward, and forms part of the inner wall of the zygomatic fossa. It gives attachment by its outer surface, to the External pterygoid; its inner surface forms part of the pterygoid fossa, and gives attachment to the Internal pterygoid. The internal pterygoid plate is much narrower and longer, curving outward, at its extremity, into a hook-like process of bone, the hamular process, around which turns the tendon of the Tensor palati muscle. On the posterior surface of the base of this plate is a small, oval, shallow depression, the scaphoid fossa, from which arises
the Tensor palati, and above which is seen the posterior orifice of the Vidian canal. Below and to the inner side of the Vidian canal, on the posterior surface of the base of this plate, is a little prominence, which is known by the name of the pterygoid tubercle. The outer surface of this plate forms part of the pterygoid fossa, the inner surface forming the outer boundary of the posterior aperture of the nares. The Superior constrictor of the pharynx is attached to its posterior edge. The two pterygoid plates are separated below by an angular interval, in which the pterygoid process, or tuberosity, of the palate bone is received. The anterior surface of the pterygoid process is very broad at its base, and forms the posterior wall of the sphenomaxillary fossa. It supports Meckel's ganglion. It presents, above, the anterior orifice of the Vidian canal; and below, a rough margin, which articulates with the perpendicular plate of the palate bone.

The Sphenoidal Spongy Bones are two thin, curved plates of bones, which exist as separate pieces until puberty, and occasionally are not joined to the palate in the adult. They are situated at the anterior and inferior part of the body of the sphenoid, an aperture of variable size being left in their anterior wall, through which the sphenoidal sinuses open into the nasal fossae. They are irregular in form and taper to a point behind, being broader and thinner in front. Their upper surface, which looks toward the cavity of the sinus, is concave; their under surface convex. Each bone articulates in front with the ethmoid, externally with the palate; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process on the outer side and the rostrum of the sphenoid on the inner.

Development.—Up to about the eighth month of foetal life the sphenoid bone consists of two distinct parts: posterior or post-sphenoid part, which comprises the pituitary fossa, the greater wings, and the pterygoid processes; and an anterior or pre-sphenoid part, to which the anterior part of the body and lesser wings belong. It is developed by fourteen centres: eight for the posterior sphenoid division, and six for the anterior sphenoid. The eight centres for the posterior sphenoid are—one for each greater wing and external pterygoid plate, one for each internal pterygoid plate, two for the posterior part of the body, and one on each side for the lingula. The six for the anterior sphenoid are one for each lesser wing, two for the anterior part of the body, and one for each sphenoidal turbinate bone.

Post-sphenoid Division.—The first nuclei to appear are those for the greater wings. They make their appearance between the foramen rotundum and foramen ovale about the eighth week, and from them the external pterygoid plates are also formed. Soon after, the nuclei for the posterior part of the body appear, one on either side of the sella turcica, and become blended together about the middle of foetal life. About the fourth month the remaining four centres appear, those for the internal pterygoid plates being ossified in membrane and becoming joined to the external pterygoid plate about the sixth month. The centres for the lingulae speedily become joined to the rest of the bone.

Pre-sphenoid Division.—The first nuclei to appear are those for the lesser wings. They make their appearance about the ninth week, at the outer borders of the optic foramina. A second pair of nuclei appear on the inner side of the

---

1 A small portion of the sphenoidal turbinate bone sometimes enters into the formation of the inner wall of the orbit, between the os planum of the ethmoid in front, the orbital plate of the palate below, and the frontal above.—Cleland, *Roy. Soc. Trans.*, 1862.
foramina shortly after, and, becoming united, form the front part of the body of the bone. The remaining two centres for the sphenoidal turbinate bones do not make their appearance until the end of the third year.

The pre-sphenoid is united to the body of the post-sphenoid about the eighth month, so that at birth the bone consists of three pieces—viz. the body in the centre, and on each side the great wings with the pterygoid processes. The lesser wings become united to the body at about the time of birth. At the first year after birth the greater wings and body are united. From the tenth to the twelfth year the spongy bones are partially united to the sphenoid, their junction being complete by the twentieth year. Lastly, the sphenoid joins the occipital from the eighteenth to the twenty-fifth year.

Articulations.—The sphenoid articulates with all the bones of the cranium, and five of the face—the two malar, two palate, and vomer: the exact extent of articulation with each bone is shown in the accompanying figures.\(^1\)

Attachment of Muscles.—To eleven pairs: the Temporal, External pterygoid, Internal pterygoid, Superior constrictor, Tensor palati, Levator palpebræ, Obliquus oculi superior, Superior rectus, Internal rectus, Inferior rectus, External rectus.

The Ethmoid Bone.

The Ethmoid (\(\mu\nu\rho\zeta\); a sieve) is an exceedingly light, spongy bone, of a cubical form, situated at the anterior part of the base of the cranium, between the two orbits, at the root of the nose, and contributing to form each of these cavities. It consists of three parts: a horizontal plate, which forms part of the base of the cranium; a perpendicular plate, which forms part of the septum nasi; and two lateral masses of cells.

The Horizontal or Cribriform Plate (Fig. 147) forms part of the anterior fossa of the base of the skull, and is received into the ethmoid notch of the frontal bone between the two orbital plates. Projecting upward from the middle line of this plate is a thick, smooth, triangular process of bone, the crista galli, so called from its resemblance to a cock’s comb. Its base joins the cribriform plate. Its posterior border, long, thin, and slightly curved, serves for the attachment of the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone, and presents two small projecting alæ, which are received into corresponding depressions in the frontal, completing the foramen cecum behind. Its sides are smooth and sometimes bulging; in which case it is found to enclose a small sinus.\(^2\) On each side of the crista galli the cribriform plate is narrow and deeply grooved, to support the bulb of the olfactory tract, and perforated by foramina for the passage of the olfactory nerves. These foramina are arranged in three rows: the innermost, which are the largest and least numerous, are lost in grooves on the upper part of the septum; the foramina of the outer row are continued on to the surface of

---

\(^1\) It also sometimes articulates with the tuberosity of the superior maxilla (see p. 190).

\(^2\) Sir George Humphry states that the crista galli is commonly inclined to one side, usually the opposite to that toward which the lower part of the perpendicular plate is bent.—*The Human Skeleton*, 1858, p. 277.)
the upper spongy bone. The foramina of the middle row are the smallest; they perforate the bone and transmit nerves to the roof of the nose. At the front part of the cribiform plate, on each side of the crista galli, is a small fissure, which transmits the nasal branch of the ophthalmic nerve; and at its posterior part a triangular notch, which receives the ethmoidal spine of the sphenoid.

The **Perpendicular Plate** (Fig. 148) is a thin, flattened lamella of bone, which descends from the under surface of the cribiform plate, and assists in forming the septum of the nose. It is much thinner in the middle than at the circumference, and is generally deflected a little to one side. Its anterior border articulates with the nasal spine of the frontal bone and crest of the nasal bones. Its posterior border, divided into two parts, articulates by its upper half with the ethmoidal crest of the sphenoid, by its lower half with the vomer. The inferior border serves for the attachment of the triangular cartilage of the nose. On each side of the perpendicular plate numerous grooves and canals are seen, leading from foramina on the cribiform plate; they lodge filaments of the olfactory nerves.

The **Lateral Masses** of the ethmoid consist of a number of thin-walled cellular cavities, the **ethmoidal cells**, interposed between two vertical plates of bone, the outer one of which forms part of the orbit, and the inner one part of the nasal fossa of the corresponding side. In the disarticulated bone many of these cells appear to be broken; but when the bones are articulated they are closed in at every part. The upper surface of each lateral mass presents a number of apparently half-broken cellular spaces; these are closed in when articulated by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves on each side, converted into canals by articulation with the frontal; they are the **anterior** and **posterior ethmoidal** foramina, and open on the inner wall of the orbit. The posterior surface also presents large, irregular cellular cavities, which are closed in by articulation with the sphenoidal turbinated bones and orbital process of the palate. The cells at the anterior surface are completed by the lachrymal bone and nasal process of the superior maxillary, and those below also by the superior maxillary. The outer surface of each lateral mass is formed of a thin, smooth, square plate of bone, called the **os planum**; it forms part of the inner wall of the orbit, and articulates, above, with the orbital plate of the frontal; below, with the superior maxillary; in front, with the lachrymal; and behind, with the sphenoid and orbital process of the palate.

From the inferior part of each lateral mass, immediately beneath the os planum, there projects downward and backward an irregular lamina of bone, called the **unciform process**, from its hook-like form; it serves to close in the upper part of the orifice of the antrum, and articulates with the ethmoidal process of the inferior turbinated bone. It is often broken in disarticulating the bones.

The inner surface of each lateral mass forms part of the outer wall of the nasal fossa of the corresponding side. It is formed of a thin lamella of bone, which descends from the under surface of the cribiform plate, and terminates below in a free, convoluted margin, the **middle turbinated** bone. The whole of this sur-
face is rough and marked above by numerous grooves, which run nearly vertically downward from the cribiform plate; they lodge branches of the olfactory nerve, which are distributed on the mucous membrane covering the bone. The back part of this surface is subdivided by a narrow oblique fissure, the superior meatus of the nose, bounded above by a thin, curved plate of bone, the superior turbinate bone. By means of an orifice at the upper part of this fissure the posterior ethmoidal cells open into the nose. Below, and in front of the superior meatus, is seen the convex surface of the middle turbinate bone. It extends along the whole length of the inner surface of each lateral mass; its lower margin is free and thick, and its concavity, directed outward, assists in forming the middle meatus. It is by a large orifice at the upper and front part of the middle meatus that the anterior ethmoidal cells, and through them the frontal sinuses, communicate with the nose by means of a funnel-shaped canal, the infundibulum. The cellular cavities of each lateral mass, thus walled in by the os planum on the outer side and by the other bones already mentioned, are divided by a thin transverse bony partition into two sets, which do not communicate with each other; they are termed the anterior and posterior ethmoidal cells or sinuses. The former, more numerous, communicate with the frontal sinuses above and the middle meatus below by means of a long, flexuous canal, the infundibulum; the posterior, less numerous, open into the superior meatus, and communicate (occasionally) with the sphenoidal sinuses.

Development.—By three centres: one for the perpendicular lamella, and one for each lateral mass.

The lateral masses are first developed, ossific granules making their appearance in the os planum between the fourth and fifth months of foetal life, and extending into the spongy bones. At birth the bone consists of the two lateral masses, which are small and ill-developed. During the first year after birth the perpendicular and horizontal plates begin to ossify, from a single nucleus, and become joined to the lateral masses about the beginning of the second year. The formation of the ethmoidal cells, which completes the bone, does not commence until about the fourth or fifth year.

Articulations.—With fifteen bones: the sphenoid, two sphenoidal turbinate, the frontal, and eleven of the face—the two nasal, two superior maxillary, two lachrymal, two palate, two inferior turbinate, and the vomer. No muscles are attached to this bone.

DEVELOPMENT OF THE CRANIUM.

The early stages of the development of the cranium have already been described (see page 115). We have seen that it is formed from a layer of mesoblast, derived from the protovertebral plates of the trunk, which is spread over the whole surface of the rudimentary brain. That portion of this layer from which the bones of the skull are to be developed consists of a thin, membranous capsule.

Ossification commences in the roof, and is preceded by the deposition of a membranous blastema upon the surface of the cerebral capsule, in which the ossifying process extends, the primitive membranous capsule becoming the internal periosteum, and being ultimately blended with the dura mater. Although the bones of the vertex of the skull appear before those at the base, and make considerable progress in their growth, at birth ossification is more advanced in the base, this portion of the skull forming a solid, immovable groundwork.
The Fontanelles.

Before birth the bones at the vertex and side of the skull are separated from each other by membranous intervals in which bone is deficient. These intervals are principally found at the four angles of the parietal bones. Hence there are six fontanelles. Their formation is due to the wave of ossification being circular and the bones quadrilateral; the ossific matter first meets at the margins of the bones, at the points nearest to their centres of ossification, and vacuities or spaces are left at the angles, which are called fontanelles, so named from the pulsations of the brain, which are perceptible at the anterior fontanelle, and were likened to the rising of water in a fountain. The anterior fontanelle is the largest, and corresponds to the junction of the sagittal and coronal sutures; the posterior fontanelle, of smaller size, is situated at the junction of the sagittal and lambdoid sutures; the remaining ones are situated at the inferior angles of each parietal bone. The latter are closed soon after birth; the two at the two superior angles remain open longer; the posterior being closed in a few months after birth; the anterior remaining open until the first or second year. These spaces are gradually filled in by an extension of the ossifying process or by the development of a Wormian bone. Sometimes the anterior fontanelle remains open beyond two years, and is occasionally persistent throughout life.

Supernumerary or Wormian 1 Bones.

In addition to the constant centres of ossification of the skull, additional ones are occasionally found in the course of the sutures. These form irregular, isolated bones, interposed between the cranial bones, and have been termed Wormian bones or osse triquetra. They are most frequently found in the course of the lambdoid suture, but occasionally also occupy the situation of the fontanelles, especially the posterior and, more rarely, the anterior. Frequently one is found between the anterior inferior angle of the parietal bone and the greater wing of the sphenoid, the petirion ossicle (Fig. 151). They have a great tendency to be symmetrical on the two sides of the skull, and they vary much in size, being in some cases not larger than a pin's head, and confined to the outer table; in other cases so large that one pair of these bones may form the whole of the occipital bone above the superior curved lines, as described by Béclard and Ward. Their number is generally limited to two or three, but more than a hundred have been found in the skull of an adult hydrocephalic skeleton. In their development, structure, and mode of articulation they resemble the other cranial bones.

Congenital Fissures and Gaps.

An arrest in the ossifying process may give rise to deficiencies or gaps; or to fissures, which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins toward the centre of the bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

BONES OF THE FACE.

The Facial Bones are fourteen in number—viz. the

Two Nasal.
Two Superior Maxillary.
Two Lachrymal.
Two Malar.
Two Palate.
Two Inferior Turbinate.
Vomer.
Inferior Maxillary.

1 Wormius, a physician in Copenhagen, is said to have given the first detailed description of these bones.
"Of these, the upper and lower jaws are the fundamental bones for mastication, and the others are accessories; for the chief function of the facial bones is to provide an apparatus for mastication, while subsidiary functions are to provide for the sense-organs (eye, nose, tongue) and a vestibule to the respiratory and vocal organs. Hence the variations in the shape of the face in man and the lower animals depend chiefly on the question of the character of their food and their mode of obtaining it."  

The Nasal Bone.

The Nasal (nasus, the nose) are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the middle and upper part of the face, forming, by their junction, "the bridge" of the nose. Each bone presents for examination two surfaces and four borders. The outer surface is concave from above downward, convex from side to side; it is covered by the Pyramidalis and Compressor nasi muscles, and give attachment at its upper part to a few fibres of the Occipito-frontalis muscle (Theile). It is marked by numerous small arterial furrows, and perforated about its centre by a foramen, sometimes double, for the transmission of a small vein. Sometimes this foramen is absent on one or both sides, and occasionally the foramen cecum opens on this surface. The inner surface is concave from side to side, convex from above downward; in which direction it is traversed by a longitudinal groove (sometimes a canal), for the passage of a branch of the nasal nerve. The superior border is narrow, thick, and serrated, for articulation with the nasal notch of the frontal bone. The inferior border is broad, thin, sharp, inclined obliquely downward, outward, and backward, and serves for the attachment of the lateral cartilage of the nose. This border presents, about its middle, a notch, through which passes the branch of the nasal nerve above referred to, and is prolonged at its inner extremity into a sharp spine, which, when articulated with the opposite bone, forms the nasal angle. The external border is serrated, bevelled at the expense of the internal surface above and of the external below, to articulate with the nasal process of the superior maxillary. The internal border, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest which forms part of the septum of the nose; this crest articulates with the nasal spine of the frontal above, and the perpendicular plate of the ethmoid below.

Development.—By one centre for each bone, which appears about the same period as in the vertebræ.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the superior maxillary.

Attachment of Muscles.—A few fibres of the Occipito-frontalis muscle.

The Superior Maxillary Bones.

The Superior Maxillary (maxilla, the jaw-bone) is one of the most important bones of the face from a surgical point of view, on account of the number of diseases to which some of its parts are liable. Its careful examination becomes, therefore, a matter of considerable interest. It is the largest bone of the face, excepting the lower jaw, and forms, by its union with its fellow of the opposite side, the whole

1 W. W. Keen, American edition, p. 185.
of the upper jaw. Each bone assists in the formation of three cavities, the roof of the mouth, the floor and outer wall of the nasal fossae, and the floor of the orbit, and also enters into the formation of two fossae, the zygomatic and sphenomaxillary, and two fissures, the sphenomaxillary and pterygo-maxillary.

The bone presents for examination a body and four processes—malar, nasal, alveolar, and palate. The body is somewhat cuboid, and is hollowed out in its interior to form a large cavity, the antrum of Highmore. Its surfaces are four—an external or facial, a posterior or zygomatic, a superior or orbital, and an internal.

The external or facial surface (Fig. 154) is directed forward and outward. Just above the incisor teeth is a depression, the incisive or myrtiform fossa, which gives origin to the Depressor alae nasi; and below it to the alveolar border is attached a slip of the Orbicularis oris. Above and a little external to it the Compressor nasi arises. More external is another depression, the canine fossa, larger and deeper than the incisive fossa, from which it is separated by a vertical ridge, the canine eminence, corresponding to the socket of the canine tooth. The canine fossa gives origin to the Levator anguli oris. Above the canine fossa is the infraorbital foramen, the termination of the infraorbital canal; it transmits the infraorbital vessels and nerve. Above the infraorbital foramen is the margin of the orbit, which affords partial attachment to the Levator labii superioris proprius. To the sharp margin of bone which bounds this surface in front and separates it from the internal surface is attached the Dilator naris posterior.

The posterior or zygomatic surface is convex, directed backward and outward, and forms part of the zygomatic fossa. It presents about its centre several apertures leading to canals in the substance of the bone; they are termed the posterior dental canals, and transmit the posterior dental vessels and nerves. At the lower part of this surface is a rounded eminence, the maxillary tuberosity, especially prominent after the growth of the wisdom-tooth, rough on its inner side for articulation with the tuberosity of the palate bone, and sometimes with the external pterygoid plate. It gives attachment to a few fibres of origin of the Internal

pterygoid muscle. Immediately above the rough surface is a groove which, running obliquely down on the inner surface of the bone, is converted into a canal by articulation with the palate-bone forming the posterior palatine canal.

The superior or orbital surface is thin, smooth, triangular, and forms part of the floor of the orbit. It is bounded internally by an irregular margin which in front presents a notch, the lacrimal notch, which receives the lachrymal bone; in the middle articulates with the os planum of the ethmoid, and behind with the orbital process of the palate bone; bounded externally by a smooth, rounded edge which enters into the formation of the sphenio-maxillary fissure, and which sometimes articulates at its anterior extremity with the orbital plate of the sphenoid; bounded in front by part of the circumference of the orbit, which is continuous on the inner side with the nasal, on the outer side with the malar, process. Along the middle line of the orbital surface is a deep groove, the infraorbital, for the passage of the infraorbital vessels and nerve. The groove commences at the middle of the outer border of this surface, and, passing forward, terminates in a canal, which subdivides into two branches. One of the canals, the infraorbital, opens just below the margin of the orbit; the other, which is smaller, runs in the substance of the anterior wall of the antrum; it is called the anterior dental canal, and transmits the anterior dental vessels and nerve to the front teeth of the upper jaw. From the back part of the infraorbital canal a second small canal is sometimes given off, which runs in the substance of the bone, and conveys the middle dental nerve to the bicuspid teeth. Occasionally, this canal is derived from the anterior dental. At the inner and fore part of the orbital surface, just external to the lachrymal groove for the nasal duct, is a depression which gives origin to the Inferior oblique muscle of the eye.

The internal surface (Fig. 155) is unequally divided into two parts by a horizontal projection of bone, the palate process: the portion above the palate process forms part of the outer wall of the nasal fosse; that below it forms part of the cavity of the mouth. The superior division of this surface presents a large, irregular opening leading into the antrum of Highmore. At the upper border of this aperture are numerous broken cellular cavities, which in the articulated skull are closed in by the ethmoid and lachrymal bones. Below the aperture is a smooth
concavity which forms part of the inferior meatus of the nasal fossae, and behind it is a rough surface which articulates with the perpendicular plate of the palate bone, traversed by a groove which, commencing near the middle of the posterior border, runs obliquely downward and forward, and forms, when completed by its articulation with the palate bone, the posterior palatine canal. In front of the opening of the antrum is a deep groove, converted into a canal by the lachrymal and inferior turbinated bones. It is called the lachrymal groove, and lodges the nasal duct. More anteriorly is a well-marked rough ridge, the inferior turbinated crest, for articulation with the inferior turbinate bone. The concavity above this ridge forms part of the middle meatus of the nose, whilst that below it forms part of the inferior meatus. The portion of this surface below the palate process is concave, rough and uneven, and perforated by numerous small foramina for the passage of nutrient vessels. It enters into the formation of the roof of the mouth.

The Antrum of Highmore, or Maxillary Sinus, is a large, pyramidal cavity hollowed out of the body of the maxillary bone: its apex, directed outward, is formed by the malar process; its base, by the outer wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the orbital, facial, and zygomatic surfaces of the body of the bone. Its inner wall, or base, presents, in the disarticulated bone, a large, irregular aperture, which communicates with the nasal fossa. The margins of this aperture are thin and ragged, and the aperture itself is much contracted by its articulation with the ethmoid above, the inferior turbinate below, and the palate bone behind. In the articulated skull this cavity communicates with the middle meatus of the nasal fossae, generally by two small apertures left between the above-mentioned bones. In the recent state usually only one small opening exists, near the upper part of the cavity, sufficiently large to admit the end of a probe, the other being closed by the lining membrane of the sinus.

Crossing the cavity of the antrum are often seen several projecting laminae of bone, similar to those seen in the sinuses of the cranium; and on its posterior wall are the posterior dental canals, transmitting the posterior dental vessels and nerves to the teeth. Projecting into the floor are several conical processes, corresponding to the roots of the first and second molar teeth; in some cases the floor is perforated by the teeth in this situation.

It is from the extreme thinness of the walls of this cavity that we are enabled to explain how a tumor growing from the antrum encroaches upon the adjacent parts, pushing up the floor of the orbit, and displacing the eyeball, projecting inward into the nose, protruding forward on to the cheek, and making its way backward into the zygomatic fossa and downward into the mouth.

The Malar Process is a rough, triangular eminence, situated at the angle of separation of the facial from the zygomatic surface. In front it is concave, forming part of the facial surface; behind it is also concave, and forms part of the zygomatic fossa; above it is rough and serrated for articulation with the malar bone; whilst below a prominent ridge marks the division between the facial and zygomatic surfaces. A small part of the Masseter muscle arises from this process.

The Nasal Process is a thick, triangular plate of bone, which projects upward, inward, and backward by the side of the nose, forming part of its lateral boundary. Its external surface is concave, smooth, perforated by numerous foramina, and gives attachment to the Levator labii superioris alaeque nasi, the Orbicularis palpebrarum, and Tendo oculi. Its internal surface forms part of the outer wall of the nose: at its upper part it presents a rough, uneven surface, which articulates with the ethmoid bone, closing in the anterior ethmoidal cells; below this is a transverse ridge, the superior turbinated crest, for articulation with the

---

1 In some cases, at any rate, the lachrymal bone encroaches slightly on the anterior superior portion of the opening, and assists in forming the inner wall of the antrum.

2 The number of teeth whose fangs are in relation with the floor of the antrum is variable. The antrum "may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the dens sphenoidii." (See Mr. Salter on Abscess of the Antrum, in a System of Surgery, edited by T. Holmes, 2d ed. vol. iv. p. 356.)
middle turbinated bone of the ethmoid, bounded below by a smooth concavity which forms part of the middle meatus; below this again is the inferior turbinated crest (already described), where the process joins the body of the bone. Its upper border articulates with the frontal bone. The anterior border of the nasal process is thin, directed obliquely downward and forward, and presents a serrated edge for articulation with the nasal bone; its posterior border is thick, and hollowed into a groove, the lachrymal groove, for the nasal duct: of the two margins of this groove, the inner one articulates with the lachrymal bone, the outer one forms part of the circumference of the orbit. Just where the latter joins the orbital surface is a small tubercle, the lachrymal tubercle: this serves as a guide to the position of the lachrymal sac in the operation for fistula lachrymalis. The lachrymal groove in the articulated skull is converted into a canal by the lachrymal bone and lachrymal process of the inferior turbinated: it is directed downward, and a little backward and outward, is about the diameter of a goose-quill, slightly narrower in the middle than at either extremity, and terminates below in the inferior meatus. It lodges the nasal duct.

The Alveolar Process is the thickest and most spongy part of the bone, broader behind than in front, and excavated into deep cavities for the reception of the teeth. These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and subdivided into minor cavities; those for the incisors are single, but deep and narrow. The Buccinator muscle arises from the outer surface of this process, as far forward as the first molar tooth.

The Palate Process, thick and strong, projects horizontally inward from the inner surface of the bone. It is much thicker in front than behind, and forms a considerable part of the floor of the nostril and the roof of the mouth.

Its inferior surface (Fig. 156) is concave, rough and uneven, and forms part of the roof of the mouth. This surface is perforated by numerous foramina for the passage of the nutrient vessels, channelled at the back part of its alveolar border by a longitudinal groove, sometimes a canal, for the transmission of the posterior palatine vessels, and the anterior and external palatine nerves from Meckel’s gan-
glion, and presents little depressions for the lodgment of the palatine glands. When the two superior maxillary bones are articulated together, a large orifice may be seen in the middle line, immediately behind the incisor teeth. This is the anterior palatine canal or fossa. This canal, as it passes through the thickness of the palate process, is divided into four compartments; that is to say, two canals branch off laterally to the right and left nasal fossae, and two canals, one in front and one behind, lie in the middle line. The former pair of these canals is named the foramina of Stenson, and through them passes the anterior or terminal branch of the descending or posterior palatine arteries, which ascend from the mouth to the nasal fossae. The remaining pair of canals is termed the foramina of Scarpa, and transmit the naso-palatine nerves, the left passing through the anterior, and the right through the posterior, canal. On the palatal surface of the process a delicate linear suture may sometimes be seen extending from the anterior palatine fossa to the interval between the lateral incisor and the canine tooth. This marks out the intermaxillary or incisive bone which in some animals exists permanently as a separate piece. It includes the whole thickness of the alveolus, the corresponding part of the floor of the nose, and the anterior nasal spine, and contains the sockets of the incisor teeth. One or two small foramina in the alveolar margin behind the incisor teeth are occasionally seen in the adult, almost constantly in the young subject. They are called the incisive foramina, and transmit vessels and nerves to the incisor teeth. The upper surface is concave from side to side, smooth, and forms part of the floor of the nose. It presents the upper orifices of the foramina of Stenson and Scarpa, the former being on each side of the middle line, the latter being situated in the intermaxillary suture, and therefore not visible unless the two bones are placed in apposition. The outer border of the palate process is incorporated with the rest of the bone. The inner border is thicker in front than behind, and is raised above into a ridge, the nasal crest, which, with the corresponding ridge in the opposite bone, forms a groove for the reception of the vomer. In front this crest rises to a considerable height, and this portion is named the incisor crest. The anterior margin is bounded by the thin, concave border of the opening of the nose, prolonged forward internally into a sharp process, forming, with a similar process of the opposite bone, the anterior nasal spine. The posterior border is serrated for articulation with the horizontal plate of the palate bone.

Development.—This bone commences to ossify at a very early period, and ossification proceeds in it with great rapidity, so that it is difficult to ascertain with certainty its precise number of centres. It appears, however, probable that it is ossified by five primary and two secondary centres. The primary centres appear about the seventh or eighth week; first, one each for the facial surface, the posterior part of the alveolus, and the orbital plate, and a few days later one for the palate process, and one for the front part of the alveolus, which carries the incisor teeth, and which corresponds to the pre-maxillary bone of the lower animals. All these, except the last, speedily fuse, and the two secondary centres, one for the nasal process and the other for the malar process, appear and join the rest of the bone. By the tenth week the bone consists of two portions—the greater part of the bone formed of six out of the seven centres and the pre-maxillary portion. The suture between these two portions on the palate persists till middle life, but is not to be seen on the facial surface. This is believed by Callender to be due to the fact that the front wall of the sockets of the incisive teeth is not formed by the pre-maxillary bone, but by an outgrowth from the facial part of the
superior maxilla. The antrum appears as a shallow groove on the inner surface of the bone at an earlier period than any of the other nasal sinuses, its development commencing about the fourth month of fetal life. The sockets for the teeth are formed by the growing downward of two plates from the dental groove, which subsequently becomes divided by partitions jutting across from the one to the other.

Articulations.—With nine bones: two of the cranium, the frontal and ethmoid, and seven of the face—viz. the nasal, malar, lachrymal, inferior turbinate, palate, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital plate of the sphenoid, and sometimes with its external pterygoid plate.

Attachment of Muscles.—To twelve: the Orbicularis palpebrarum, Obliquus oculi inferior, Levator labii superioris alaeque nasi, Levator labii superioris proprius, Levator anguli oris, Compressor nasi, Depressor alae nasi, Dilatator nasis posterior, Masseter, Buccinator, Internal pterygoid, and Orbicularis oris.

CHANGES PRODUCED IN THE UPPER JAW BY AGE.

At birth and during infancy the diameter of the bone is greater in an antero-posterior than in a vertical direction. Its nasal process is long, its orbital surface large, and its tuberosity well marked. In the adult the vertical diameter is the greater, owing to the development of the alveolar process and the increase in size of the antrum. In old age the bone approaches again in character to the infantile condition: its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and diminished in thickness.

The Lachrymal Bones.

The Lachrymal (lachryma, a tear) are the smallest and most fragile bones of the face. They are situated at the front part of the inner wall of the orbit, and resemble somewhat in form, thinness, and size, a finger-nail; hence they are termed the ossa unguis. Each bone presents for examination two surfaces and four borders. The external or orbital surface (Fig. 158) is divided by a vertical ridge, the lachrymal crest, into two parts. The portion of bone in front of this ridge presents a smooth, concave, longitudinal groove, the free margin of which unites with the nasal process of the superior maxillary bone, completing the lachrymal groove. The upper part of this groove lodges the lachrymal sac; the lower part lodges the nasal duct. The portion of bone behind the ridge is smooth, slightly concave, and forms part of the inner wall of the orbit. The ridge, with a part of the orbital surface immediately behind it, affords attachment to the Tensor tarsi: the ridge terminates below in a small, hook-like projection, the hamular process, which articulates with the lachrymal tubercle of the superior maxillary bone, and completes the upper orifice of the lachrymal groove. It sometimes exists as a separate piece, which is then called the lesser lachrymal bone. The internal or nasal surface presents a depressed furrow, corresponding to the ridge on its outer surface. The surface of bone in front of this forms part of the middle meatus, and that behind it articulates with the ethmoid bone, filling in the anterior ethmoidal cells. Of the four borders, the anterior is the longest, and articulates with the nasal process of the superior maxillary bone. The posterior, thin and uneven, articulates with the os planum of the ethmoid. The superior, the shortest and thickest, articulates with the internal angular process of the frontal bone. The inferior is divided by the lower edge of the vertical crest into two parts; the posterior part articulates with the orbital plate of the superior maxillary bone; the anterior portion is prolonged downward into a pointed process, which articulates with the lachrymal process of the inferior turbinate bone and assists in the formation of the lachrymal groove.
Development.—By a single centre, which makes its appearance soon after ossification of the vertebrae has commenced.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the superior maxillary and the inferior turbinate.

Attachment of Muscles.—To one muscle, the Tensor tarsi.

The Malar Bones.

The Malar (mala, the cheek) are two small, quadrangular bones, situated at the upper and outer part of the face: they form the prominence of the cheek, part of the outer wall and floor of the orbit, and part of the temporal and zygomatic fossae. Each bone presents for examination an external and an internal surface; four processes, the frontal, orbital, maxillary, and zygomatic; and four borders. The external surface (Fig. 159) is smooth, convex, perforated near its centre by one or two small apertures, the malar foramina, for the passage of nerves and vessels, covered by the Orbicularis palpebrarum muscle, and affords attachment to the Zygomaticus major and minor muscles.

The internal surface (Fig. 160), directed backward and inward, is concave, presenting internally a rough, triangular surface, for articulation with the super-
THE PALATE BONES.

Wormian bone in the angular interval between them. On the upper surface of the orbital process are seen the orifices of one or two temporo-malar canals; one of these usually opens on the posterior surface, the other (occasionally two) on the facial surface: they transmit filaments (temporo-malar) of the orbital branch of the superior maxillary nerve. The maxillary process is a rough, triangular surface which articulates with the superior maxillary bone. The zygomatic process, long, narrow, and serrated, articulates with the zygomatic process of the temporal bone. Of the four borders, the antero-superior or orbital is smooth, arched, and forms a considerable part of the circumference of the orbit. The antero-inferior or maxillary border is rough, and bevelled at the expense of its inner table, to articulate with the superior maxillary bone; affording attachment by its margin to the Levator labii superioris proprius, just at its point of junction with the superior maxillary. The postero-superior or temporal border, curved like an italic letter f, is continuous above with the commencement of the temporal ridge; below, with the upper border of the zygomatic arch: it affords attachment to the temporal fascia. The postero-inferior or zygomatic border is continuous with the lower border of the zygomatic arch, affording attachment by its rough edge to the Masseter muscle.

Development.—The malar bone ossifies generally from two, but occasionally from three, centres. One, which forms the chief part of the bone, appears about the seventh week, near the orbital margin. The second appears somewhat later, along the lower margin. The third, when it exists, is found in the hinder border. The bone is sometimes, after birth, seen to be divided by a horizontal suture into an upper and larger division and a lower and smaller. This divided condition is probably due to the persistent separation of the two centres of ossification. In some quadrumana the malar bone consists of two parts, an orbital and a malar, which are ossified by separate centres.

Articulations.—With four bones: three of the cranium, frontal, sphenoid, and temporal; and one of the face, the superior maxillary.

Attachment of Muscles.—To five: The Levator labii superioris proprius, Zygomaticus major and minor, Masseter, and Temporal.

The Palate Bones (palatum, the palate) are situated at the back part of the nasal fossae: they are wedged in between the superior maxillary bones and the pterygoid processes of the sphenoid. Each bone assists in the formation of three cavities: the floor and outer wall of the nose, the roof of the mouth, and the floor of the orbit, and enters into the formation of two fossae, the sphen-maxillary and pterygoid; and one fissure, the sphen-maxillary. In form the palate bone somewhat resembles the letter L, and may be divided into an inferior or horizontal plate and a superior or vertical plate.

The Horizontal Plate is thick, of a quadrilateral form, and presents two surfaces and four borders. The superior surface, concave from side to side, forms the back part of the floor of the nostril. The inferior surface, slightly concave and rough, forms the back part of the hard palate. At its posterior part may be seen a transverse ridge, more or less marked, for the attachment of part of the aponeurosis of the Tensor palati muscle. At the outer extremity of this ridge is a deep groove converted into a canal by its articulation with the tuberosity of the superior maxillary bone, and forming the posterior palatine canal. Near this groove the orifices of one or two small canals, accessory posterior palatine, may be seen. The anterior border is serrated, bevelled at the expense of its inferior surface, and articulates with the palate process of the superior maxillary bone. The posterior border is concave, free, and serves for the attachment of the soft palate. Its inner extremity is sharp and pointed, and, when united with the opposite bone, forms a projecting process, the posterior nasal spine, for the attachment of the Azygos uvulae. The external border is united with the lower part of the perpen-
dicular plate almost at right angles. The internal border, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the opposite bone, forms a crest in which the vomer is received.

The Vertical Plate (Fig. 161) is thin, of an oblong form, and directed upward and a little inward. It presents two surfaces, an external and an internal, and four borders.

The internal surface presents at its lower part a broad, shallow depression, which forms part of the inferior meatus of the nose. Immediately above this is a well-marked horizontal ridge, the inferior turbinated crest, for articulation with the inferior turbinated bone; above this, a second broad, shallow depression, which forms part of the middle meatus, surmounted above by a horizontal ridge less prominent than the inferior, the superior turbinated crest, for articulation with the middle turbinated bone. Above the superior turbinated crest is a narrow, horizontal groove, which forms part of the superior meatus.

The external surface is rough and irregular throughout the greater part of its extent, for articulation with the inner surface of the superior maxillary bone, its upper and back part being smooth where it enters into the formation of the sphenomaxillary fossa; it is also smooth in front, where it covers the orifice of the antrum. Toward the back part of this surface is a deep groove, converted into a canal, the posterior palatine, by its articulation with the superior maxillary bone. It transmits the posterior or descending palatine vessels and one of the descending palatine branches from Meckel's ganglion.

The anterior border is thin, irregular, and presents, opposite the inferior turbinated crest, a pointed, projecting lamina, the maxillary process, which is directed forward, and closes in the lower and back part of the opening of the antrum. The posterior border (Fig. 162) presents a deep groove, the edges of which are serrated for articulation with the pterygoid process of the sphenoid. At the lower part of this border is seen a pyramidal process of bone, the pterygoid process or tuberosity of the palate, which is received into the angular interval between the two pterygoid plates of the sphenoid at their inferior extremity. This process presents at its back part a median groove and two lateral surfaces. The groove is smooth, and forms part

![Horizontal Plate.](image)

**Fig. 161.—Left palate bone. Internal view. (Enlarged.)**

![External Surface.](image)

**Fig. 162.—Left palate bone. Posterior view. (Enlarged.)**
of the pterygoid fossa, affording attachment to the Internal pterygoid muscle; whilst the lateral surfaces are rough and uneven, for articulation with the anterior border of each pterygoid plate. A few fibres of the Superior constrictor arise from the tuberosity of the palate bone. The base of this process, continuous with the horizontal portion of the bone, presents the apertures of the accessory descending palatine canals, through which pass the two smaller descending branches of Meckel's ganglion; whilst its outer surface is rough for articulation with the inner surface of the body of the superior maxillary bone.

The superior border of the vertical plate presents two well-marked processes separated by an intervening notch or foramen. The anterior, or larger, is called the orbital process; the posterior, the sphenoidal.

The Orbital Process, directed upward and outward, is placed on a higher level than the sphenoidal. It presents five surfaces, which enclose a hollow cellular cavity, and is connected to the perpendicular plate by a narrow, constricted neck. Of these five surfaces, three are articular, two non-articular or free surfaces. The three articular are the anterior or maxillary surface, which is directed forward, outward, and downward, is of an oblong form, and rough for articulation with the superior maxillary bone. The posterior or sphenoidal surface is directed backward, upward, and inward. It ordinarily presents a small, open cell, which communicates with the sphenoidal cells, and the margins of which are serrated for articulation with the vertical part of the sphenoidal turbinated bone. The internal or ethmoidal surface is directed inward, upward, and forward, and articulates with the lateral mass of the ethmoid bone. In some cases the cellular cavity above mentioned opens on this surface of the bone; it then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates both with the posterior ethmoidal and the sphenoidal cells. The non-articular or free surfaces are the superior or orbital, directed upward and outward, of triangular form, concave, smooth, and forming the back part of the floor of the orbit; and the external or zygomatic surface, directed outward, backward, and downward, of an oblong form, smooth, lying in the spheno-maxillary fossa, and looking into the zygomatic fossa. The latter surface is separated from the orbital by a smooth, rounded border, which enters into the formation of the spheno-maxillary fissure.

The Sphenoidal Process of the palate bone is a thin, compressed plate, much smaller than the orbital, and directed upward and inward. It presents three surfaces and two borders. The superior surface, the smallest of the three, articulates with the under surface of the sphenoidal turbinated bone; it presents a groove, which contributes to the formation of the pterygo-palatine canal. The internal surface is concave, and forms part of the outer wall of the nasal fossa. The external surface is divided into an articular and a non-articular portion: the former is rough, for articulation with the inner surface of the pterygoid process of the sphenoid; the latter is smooth, and forms part of the spheno-maxillary fossa. The anterior border forms the posterior boundary of the spheno-palatine foramen. The posterior border, serrated at the expense of the outer table, articulates with the inner surface of the pterygoid process.

The orbital and sphenoidal processes are separated from one another by a deep notch, which is converted into a foramen, the sphenopala tine, by articulation with the sphenoidal turbinated bone. Sometimes the two processes are united above, and form between them a complete foramen, or the notch is crossed by one or more spicule of bone, so as to form two or more foramina. In the articulated skull this foramen opens into the back part of the outer wall of the superior meatus, and transmits the spheno-palatine vessels and the superior nasal and naso-palatine nerves.

Development.—From a single centre, which makes its appearance about the second month at the angle of junction of the two plates of the bone. From this point ossification spreads inward to the horizontal plate, downward into the tuberosity, and upward into the vertical plate. In the fetus the horizontal plate
is much longer than the vertical, and even after it is fully ossified the whole bone is at first remarkable for its shortness.

Articulations.—With six bones: the sphenoid, ethmoid, superior maxillary, inferior turbinate, vomer, and opposite palate.

Attachment of Muscles.—To four: the Tensor palati, Azygos uvulae, Internal pterygoid, and Superior constrictor of the pharynx.

The Inferior Turbinated Bones.

The Inferior Turbinated Bones (turbo, a whirl) are situated on each side of the outer wall of the nasal fossae. Each consists of a layer of thin, spongy bone, curled upon itself like a scroll—hence its name "turbinated"—and extends horizontally along the outer wall of the nasal fossa, immediately below the orifice of the antrum. Each bone presents two surfaces, two borders, and two extremities.

The internal surface (Fig. 163) is convex, perforated by numerous apertures, and traversed by longitudinal grooves and canals for the lodgment of arteries and veins. In the recent state it is covered by the lining membrane of the nose. The external surface is concave (Fig. 164), and forms part of the inferior meatus. Its upper border is thin, irregular, and connected to various bones along the outer wall of the nose. It may be divided into three portions: of these, the anterior articulates with the inferior turbinate crest of the superior maxillary bone; the posterior with the inferior turbinate crest of the palate bone; the middle portion of the superior border presents three well-marked processes, which vary much in their size and form. Of these, the anterior and smallest is situated at the junction of the anterior fourth with the posterior three-fourths of the bone; it is small and pointed, and is called the lachrymal process; it articulates by its apex with the anterior inferior angle of the lachrymal bone, and by its margins with the groove on the back of the nasal process of the superior maxillary, and thus assists in forming the canal for the nasal duct. At the junction of the two middle fourths of the bone, but encroaching on its posterior fourth, a broad, thin plate, the ethmoidal process, ascends to join the unciniform process of the ethmoid; from the lower border of this process a thin lamina of bone curves downward and outward, articulating by its lower margin with the lower edge of the orifice of the antrum; it is called the maxillary process, and fixes the bone firmly on to the outer wall of the nasal fossa. The inferior border is free, thick, and cellular in structure, more especially in the middle of the bone. Both extremities are more or less narrow and pointed, the posterior being the more tapering. If the bone is held so that its outer concave surface is directed backward (i. e. toward the holder), and its superior border, from which the lachrymal and ethmoidal processes project, upward, the lachrymal process will be directed to the side to which the bone belongs.1

Development.—By a single centre, which makes its appearance about the middle of foetal life.

Articulations.—With four bones: one of the cranium, the ethmoid, and three of the face, the superior maxillary, lachrymal, and palate.

No muscles are attached to this bone.

1 If the lachrymal process is broken off, as is often the case, the side to which the bone belongs may be known by recollecting that the maxillary process is nearer the back than the front of the bone.
The Vomer.

The Vomer (vomer, a plough-share) is a single bone, situated vertically at the back part of the nasal fossae, forming part of the septum of the nose. It is thin, somewhat like a ploughshare in form; but it varies in different individuals, being frequently bent to one or the other side; it presents for examination two surfaces and five borders. The lateral surfaces are smooth, marked by small furrows for the lodgment of blood-vessels, and by a groove on each side, sometimes a canal, the naso-palatine, which runs obliquely downward and forward to the intermaxillary suture; it transmits the naso-palatine nerve. The posterio-superior border, the thickest, presents a deep groove, bounded on each side by a horizontal projecting ala of bone; the groove receives the rostrum of the sphenoid, whilst the alæ are overlapped and retained by laminae (the vaginal processes) which project from the under surface of the body of the sphenoid at the base of the pterygoid processes. At the front of the groove a fissure is left for the transmission of blood-vessels to the substance of the bone. The inferior border, the longest, is broad and uneven in front, where it articulates with the two superior maxillary bones; thin and sharp behind, where it joins with the palate bones. The upper half of the antero-superior border usually consists of two laminae of bone, between which is received the perpendicular plate of the ethmoid; the lower half, also separated into two laminae, receives between them the lower margin of the triangular cartilage of the nose. The anterior border is short and vertical, and articulates with the posterior margin of the incisor crest of each superior maxilla. The posterior border is free, concave, and separates the nasal fossæ behind. It is thick and bifid above, thin below.

The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, with the intervention of very little, if any, submucous connective tissue.

Development.—The vomer at an early period consists of two laminae, separated by a very considerable interval, and enclosing between them a plate of cartilage, which is prolonged forward to form the remainder of the septum. Ossification commences in it by a single centre about the eighth week. From this nucleus the two laminae are formed. They begin to coalesce at the lower part, but their union is not complete until after puberty.

Articulations.—With six bones: two of the cranium, the sphenoid and ethmoid; and four of the face, the two superior maxillary and the two palate bones; and with the cartilage of the septum.

The vomer has no muscles attached to it.

The Inferior Maxillary Bone.

The Inferior Maxillary Bone (the Mandible), the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the body, and two perpendicular portions, the rami, which join the back part of the body nearly at right angles.

The Horizontal Portion or Body (Fig. 166), is convex in its general outline, and curved somewhat like a horseshoe. It presents for examination two surfaces and two borders. The external surface is convex from side to side, concave from
above downward. In the median line is a vertical ridge, the **symphysis**, which extends from the upper to the lower border of the bone, and indicates the point of junction of the two pieces of which the bone is composed at an early period of life. The lower part of the ridge terminates in a prominent triangular eminence, the **mental process**. This eminence is rounded below, and often presents a median depression separating two processes, the **mental tubercles**. It forms the chin, a feature peculiar to the human skull. On either side of the symphysis, just below the cavities for the incisor teeth, is a depression, the **incisive fossa**, for the attachment of the Levator menti (or Levator labii inferioris); more externally is attached a portion of the Orbicularis oris (Accessory Orbicularis inferioris), and, still more externally, a foramen, the **mental foramen**, for the passage of the mental vessels and nerve. This foramen is placed just below the interval between the two bicuspids teeth. Running outward from the base of the mental process on each side is a ridge, the **external oblique** line. The ridge is at first nearly horizontal, but afterward inclines upward and backward, and is continuous with the anterior border of the **ramus**; it affords attachment to the **Depressor labii inferioris** and **Depressor anguli oris**; below it the **Platysma myoides** is attached.

The **internal surface** (Fig. 167) is concave from side to side, convex from above downward. In the middle line is an indistinct linear depression, corresponding to the symphysis externally; on either side of this depression, just below its centre, are four prominent tubercles, placed in pairs, two above and two below; they are called the **genial tubercles** or **mental spines**, and afford attachment, the upper to the **Genio-hyo-glossi**, the lower to the **Genio-hyoidi** muscles. Sometimes the tubercles on each side are blended into one; at others they all unite into an irregular eminence; or, again, nothing but an irregularity may be seen on the surface of the bone at this part. On either side of the genial tubercles is an oval depression, the **sublingual fossa**, for lodging the sublingual gland; and beneath the fossa a rough depression on each side which gives attachment to the anterior belly of the **Digastric** muscle. At the back part of the sublingual fossa the **internal oblique line** (**mylo-hyoidian**) commences; it is at first faintly marked, but becomes more distinct as it passes upward and outward, and is especially prominent opposite the last two molar teeth; it affords attachment throughout its whole extent to the **Mylo-hyoid** muscle; the Superior constrictor of the pharynx with the pterygomaxillary ligament being attached above its posterior extremity, near the alveolar margin. The portion of the bone above this ridge is smooth, and covered by the
nucous membrane of the mouth; the portion below presents an oblong depression, the submaxillary fossa, wider behind than in front, for the lodgment of the sub-

maxillary gland. The external oblique line and the internal or mylo-hyoidean line divide the body of the bone into a superior or alveolar and an inferior or basilar portion.

The superior or alveolar border is wider, and its margins thicker, behind than in front. It is hollowed into numerous cavities, for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. To its outer side, the Buccinator muscle is attached as far forward as the first molar tooth. The inferior border is rounded, longer than the superior, and thicker in front than behind; it presents a shallow groove, just where the body joins the ramus, over which the facial artery turns.

The Perpendicular Portions, or Rami, are of a quadrilateral form. Each presents for examination two surfaces, four borders, and two processes. The external surface is flat, marked with ridges, and gives attachment throughout nearly the whole of its extent to the Masseter muscle. The internal surface presents about its centre the oblique aperture of the inferior dental canal, for the passage of the inferior dental vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the lingula, which gives attachment to the internal lateral ligament of the lower jaw, and at its lower and back part a notch leading to a groove, the mylo-hyoidean, which runs obliquely downward to the back part of the submaxillary fossa, and lodges the mylo-hyoid vessels and nerve. Behind the groove is a rough surface, for the insertion of the Internal pterygoid muscle. The inferior dental canal runs obliquely downward and forward in the substance of the ramus, and then horizontally forward in the body; it is here placed under the alveoli, with which it communicates by small openings. On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals, which run forward, to be lost in the cancellous tissue of the bone beneath the incisor teeth. This canal, in the posterior two-thirds of the bone, is situated nearer the internal surface of the jaw; and in the anterior third, nearer its external surface. Its walls are composed of compact tissue at either extremity, and of cancellous in the centre. It contains the inferior dental vessels and nerve, from which branches are distributed to the teeth through small apertures at the bases of the alveoli. The
lower border of the ramus is thick, straight, and continuous with the body of the bone. At its junction with the posterior border is the angle of the jaw, which is either inverted or everted, and marked by rough, oblique ridges on each side, for the attachment of the Masseter externally, and the Internal pterygoid internally; the stylo-maxillary ligament is attached to the bone between these muscles. The anterior border is thin above, thicker below, and continuous with the external oblique line. The posterior border is thick, smooth, rounded, and covered by the parotid gland. The upper border of the ramus is thin, and presents two processes, separated by a deep concavity, the sigmoid notch. Of these processes, the anterior is the coronoid, the posterior the condyloid.

The Coronoid Process is a thin, flattened, triangular eminence of bone, which varies in shape and size in different subjects, and serves chiefly for the attachment of the Temporal muscle. Its external surface is smooth, and affords attachment to the Temporal muscle. Its internal surface gives attachment to the Temporal muscle, and presents the commencement of a longitudinal ridge, which is continued to the posterior part of the alveolar process. On the outer side of this ridge is a deep groove, continued below on the outer side of the alveolar process; this ridge and part of the groove afford attachment, above, to the Temporal; below, to the Buccinator muscle.

The Condyloid Process, shorter but thicker than the coronoid, consists of two portions: the condyle, and the constricted portion which supports the condyle, the neck. The condyle is of an oblong form, its long axis being transverse, and set obliquely on the neck in such a manner that its outer end is a little more forward and a little higher than its inner. It is convex from before backward and from side to side, the articular surface extending farther on the posterior than on the anterior aspect. The neck of the condyle is flattened from before backward, and strengthened by ridges which descend from the fore part and sides of the condyle. Its lateral margins are narrow, and present externally a tubercle for the external lateral ligament. Its posterior surface is convex; its anterior is hollowed out on its inner side by a depression (the pterygoid fossa), for the attachment of the External pterygoid.

The Sigmoid Notch, separating the two processes, is a deep semilunar depression, crossed by the masseteric vessels and nerve.

Development.—The lower jaw is developed principally from membrane, but partly from cartilage. The process of ossification commences early—before, indeed, any bone except the clavicle. Between the fifth and sixth week a centre of ossification appears in the membrane on the outer surface of Meckel’s cartilage (see page 118), from which the greater part of the bone is formed. A second centre appears in the membrane on the inner surface of the tooth-sockets, from which the inner wall of the sockets of the teeth is formed; this terminates above in the lingula. The anterior extremity of Meckel’s cartilage becomes ossified, forming the body of the bone on each side of the symphysis. And, finally, two supplemental patches of cartilage appear at the condyle and at the angle, in which centres of ossification for these parts appear. At birth the bone consists of two halves, united by a fibrous symphysis, in which ossification takes place during the first year.

Articulation.—With the glenoid fosse of the two temporal bones.

Attachment of Muscles.—To fifteen pairs: to its external surface, commencing at the symphysis, and proceeding backward: Levator menti, Depressor labii inferioris, Depressor anguli oris, Platysma myoides, Buccinator, Masseter; a portion of the Orbicularis oris (Accessory orbicularis inferioris) is also attached to this surface. To its internal surface, commencing at the same point: Genio-hyoglossus, Genio-hyoideus, Mylo-hyoideus, Digastric, Superior constrictor, Temporal, Internal pterygoid, External pterygoid.

CHANGES PRODUCED IN THE LOWER JAW BY AGE.

The changes which the lower jaw undergoes after birth relate (1) to the alterations effected in the body of the bone by the first and second dentitions, the loss of the teeth in the aged, and
THE INFERIOR MAXILLARY BONE.

SIDE VIEW OF THE LOWER JAW AT DIFFERENT PERIODS OF LIFE.

Fig. 168.—At birth.

Fig. 169.—At 7 years.

Fig. 170.—In the adult.

Fig. 171.—In old age.
the subsequent absorption of the alveoli; (2) to the size and situation of the dental canal; and (3) to the angle at which the ramus joins with the body.

At birth (Fig. 168) the bone consists of lateral halves, united by fibrous tissue. The body is a mere shell of bone, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned from one another. The dental canal is of large size, and runs near the lower border of the bone, the mental foramen opening beneath the socket of the first molar. The angle is obtuse (175°), and the condyloid portion nearly in the same horizontal line with the body; the neck of the condyle is short, and bent backward. The coronoid process is of comparatively large size, and situated at right angles with the rest of the bone.

After birth (Fig. 169) the two segments of the bone become joined at the suture, from below upward, in the first year; but a trace of separation may be visible in the beginning of the second year near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body becomes greater, owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion, which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The dental canal after the second dentition is situated just above the level of the mylo-hyoid ridge, and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth. (About the fourth year it is 140°.)

In the adult (Fig. 170) the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower border of the bone, and the dental canal runs nearly parallel with the mylo-hyoid line. The ramus is almost vertical in direction, and joins the body nearly at right angles.

In old age (Fig. 171) the bone becomes greatly reduced in size; for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains; consequently, the chief part of the bone is below the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The rami are oblique in direction, the angle obtuse, and the neck of the condyle more or less bent backward.

**The Sutures.**

The bones of the cranium and face are connected to each other by means of Sutures. That is, the articulating surfaces or edges of the bones are more or less roughened or uneven, and are closely adapted to each other, a small amount of intervening fibrous tissue fastening them together. The Cranial Sutures may be divided into three sets: 1. Those at the vertex of the skull. 2. Those at the side of the skull. 3. Those at the base.

The sutures at the vertex of the skull are three: the sagittal, coronal, and lambdoid.

The Sagittal Suture (interparietal) is formed by the junction of the two parietal bones, and extends from the middle of the frontal bone backward to the superior angle of the occipital. In childhood, and occasionally in the adult, when the two halves of the frontal bone are not united, it is continued forward to the root of the nose. This suture is sometimes perforated, near its posterior extremity, by the parietal foramen; and in front, where it joins the coronal suture, a space is occasionally left which encloses a large Wormian bone.

The Coronal Suture (fronto-parietal) extends transversely across the vertex of the skull, and connects the frontal with the parietal bones. It commences at the extremity of the greater wing of the sphenoid on one side, and terminates at the same point on the opposite side. The dentations of the suture are more marked at the sides than at the summit, and are so constructed that the frontal rests on the parietal above, whilst laterally the frontal supports the parietal.

The Lambdoid Suture (occipito-parietal), so called from its resemblance to the Greek letter Λ, connects the occipital with the parietal bones. It commences on each side at the mastoid portion of the temporal bone, and inclines upward to the end of the sagittal suture. The dentations of this suture are very deep and distinct, and are often interrupted by several small Wormian bones.

The sutures at the side of the skull extend from the external angular process of the frontal bone to the lower end of the lambdoid suture behind. The anterior portion is formed between the lateral part of the frontal bone above and the malar and great wing of the sphenoid below, forming the fronto-malar and fronto-
**THE SUTURES.**

sphenoidal sutures. These sutures can also be seen in the orbit, and form part of the so-called transverse facial suture. The posterior portion is formed between the parietal bone above and the great wing of the sphenoid, the squamous and mastoid portions of the temporal bone, forming the sphenoparietal, squamo-parietal, and masto-parietal sutures.

The Sphenoparietal is very short: it is formed by the tip of the great wing of the sphenoid, which overlaps the anterior inferior angle of the parietal bone.

The Squamo-parietal, or Squamous Suture, is arched. It is formed by the squamous portion of the temporal bone overlapping the middle division of the lower border of the parietal.

The Masto-parietal is a short suture, deeply dentated, formed by the posterior inferior angle of the parietal and the superior border of the mastoid portion of the temporal.

The sutures at the base of the skull are the basilar in the centre, and on each side the petro-occipital, the masto-occipital, the petro-sphenoidal, and the squamosphenoidal.

The Basilar Suture is formed by the junction of the basilar surface of the occipital bone with the posterior surface of the body of the sphenoid. At an early period of life a thin plate of cartilage exists between these bones, but in the adult they become fused into one. Between the outer extremity of the basilar suture and the termination of the lambdoid an irregular suture exists, which is subdivided into two portions. The inner portion, formed by the union of the petrous part of the temporal with the occipital bone, is termed the petro-occipital. The outer portion, formed by the junction of the mastoid part of the temporal with the occipital, is called the masto-occipital. Between the bones forming the petro-occipital suture a thin plate of cartilage exists; in the masto-occipital is occasionally found the opening of the mastoid foramen. Between the outer extremity of the basilar suture and the sphenoparietal an irregular suture may be seen, formed by the union of the sphenoid with the temporal bone. The inner and smaller portion of this suture is termed the petro-sphenoidal; it is formed between the petrous portion of the temporal and the great wing of the sphenoid: the outer portion, of greater length and arched, is formed between the squamous portion of the temporal and the great wing of the sphenoid; it is called the squamosphenoidal.

The cranial bones are connected with those of the face, and the facial bones with each other, by numerous sutures, which, though distinctly marked, have received no special names. The only remaining suture deserving especial consideration is the transverse. This extends across the upper part of the face, and is formed by the junction of the frontal with the facial bones: it extends from the external angular process of one side to the same point on the opposite side, and connects the frontal with the malar, the sphenoid, the ethmoid, the lachrymal, the superior maxillary, and the nasal bones on each side.

The sutures remain separate for a considerable period after the complete formation of the skull. It is probable that they serve the purpose of permitting the growth of the bones at their margins, while their peculiar formation, together with the interposition of the sutural ligament between the bones forming them, prevents the dispersion of blows or jars received upon the skull. Humphry remarks, "that, as a general rule, the sutures are first obliterated at the parts in which the ossification of the skull was last completed—viz. in the neighborhood of the fontanelles; and the cranial bones seem in this respect to observe a similar law to that which regulates the union of the epiphyses to the shafts of the long bones." The same author remarks that the time of their disappearance is extremely variable: they are sometimes found well marked in skulls edentulous with age, while in others which have only just reached maturity they can hardly be traced.
THE SKULL AS A WHOLE.

The Skull, formed by the union of the several cranial and facial bones already described, when considered as a whole is divisible into five regions: a superior region or vertex, an inferior region or base, two lateral regions, and an anterior region, the face.

The Vertex of the Skull.

The Superior Region, or Vertex, presents two surfaces, an external and an internal.

The external surface is bounded, in front, by the glabella and supraorbital ridges; behind, by the occipital protuberance and superior curved lines of the occipital bone; laterally, by an imaginary line extending from the outer end of the superior curved line, along the temporal ridge, to the external angular process of the frontal. This surface includes the vertical portion of the frontal, the greater part of the parietal, and the superior third of the occipital bone; it is smooth, convex, of an elongated oval form, crossed transversely by the coronal suture, and from before backward, by the sagittal, which terminates behind in the lambdoid. The point of junction of the coronal and sagittal sutures is named the bregma, and is represented by a line drawn vertically upward from the external auditory meatus, the head being in its normal position. The point of junction of the sagittal and lambdoid sutures is called the lambda, and is about 2 ¼ inches above the external occipital protuberance. From before backward may be seen the frontal eminences and remains of the suture connecting the two lateral halves of the frontal bone; on each side of the sagittal suture are the parietal foramen and parietal eminence, and still more posteriorly the convex surface of the occipital bone. In the neighborhood of the parietal foramen the skull is often flattened, and to this region the name of obelion is sometimes given.

The internal surface is concave, presents eminences and depressions for the convolutions of the cerebrum, and numerous furrows for the lodgment of branches of the meningeal arteries. Along the middle line of this surface is a longitudinal groove, narrow in front, where it commences at the frontal crest, but broader behind, where it lodges the superior longitudinal sinus, and by its margin affords attachment to the falx cerebri. On either side of it are several depressions for the Pacchionian bodies, and at its back part the internal openings of the parietal foramina. This surface is crossed, in front, by the coronal suture; from before backward by the sagittal; behind, by the lambdoid.

The Base of the Skull.

The Inferior Region, or Base of the Skull, presents two surfaces—an internal or cerebral, and an external or basilar.

The internal or cerebral surface (Fig. 172) presents three fossae, called the anterior, middle, and posterior fosse of the cranium.

The Anterior Fossa is formed by the orbital plates of the frontal, the cribiform plate of the ethmoid, the anterior third of the superior surface of the body, and the upper surface of the lesser wings of the sphenoid. It is the most elevated of the three fossae, convex externally where it corresponds to the roof of the orbit, concave in the median line in the situation of the cribiform plate of the ethmoid. It is traversed by three sutures, the ethmo-frontal, ethmo-sphenoidal, and fronto-sphenoidal, and lodges the frontal lobe of the cerebrum. It presents, in the median line, from before backward, the commencement of the groove for the superior longitudinal sinus and the frontal crest for the attachment of the falx cerebri; the foramen cecum, an aperture formed between the frontal bone and the crista galli of the ethmoid, which, if pervious, transmits a small vein from the nose to the superior longitudinal sinus; behind the foramen cecum, the crista galli, the posterior margin of which affords attachment to the falx cerebri; on either side of the crista galli, the olfactory groove, which supports the bulb of the olfactory...
tract, and presents three rows of foramina for its filaments, and in front a slit-like opening for the nasal branch of the ophthalmic division of the fifth nerve. On
the slit-like opening above mentioned; whilst the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits the posterior ethmoidal vessels. Farther back in the middle line is the \textit{ethmoidal spine}, bounded behind by an elevated ridge, separating two longitudinal grooves which support the olfactory tracts. Behind this is a transverse sharp ridge, running outward on either side to the anterior margin of the optic foramen, and separating the anterior from the middle fossa of the base of the skull. The anterior fossa presents, laterally, eminences and depressions for the convolutions of the brain and grooves for the lodgment of the anterior meningeal arteries.

The \textbf{Middle Fossa}, somewhat deeper than the preceding, is narrow in the middle line, but becomes wider at the side of the skull. It is bounded in front by the posterior margin of the lesser wing of the sphenoid, the anterior clinoid process, and the ridge forming the anterior margin of the optic groove; behind, by the superior border of the petrous portion of the temporal and the dorsum ephippi; externally by the squamos portion of the temporal, anterior inferior angle of the parietal bone, and greater wing of the sphenoid. It is traversed by four sutures, the squamo-parietal, sphenoparietal, squamo-sphenoidal, and petro-sphenoidal.

In the middle line, from before backward, is the \textit{optic groove}, which supports the optic commissure, and terminates on each side in the optic foramen, for the passage of the optic nerve and ophthalmic artery; behind the optic groove is the \textit{olivary process}, and laterally the \textit{anterior clinoid processes}, to which are attached processes of the tentorium cerebelli. Farther back is the \textit{septa turcica}, a deep depression which lodges the pituitary gland, bounded in front by a small eminence on either side, the \textit{middle clinoid process}, and behind by a broad square plate of bone, the \textit{dorsum ephippi}, surmounted at each superior angle by a tubercle, the \textit{posterior clinoid process}; beneath the latter process is a notch, for the sixth nerve. On each side of the \textit{septa turcica} is the \textit{cavernous groove}: it is broad, shallow, and curved somewhat like the italic letter \textit{f}; it commences behind at the foramen lacerum medium, and terminates on the inner side of the anterior clinoid process, and presents along its outer margin a ridge of bone. This groove lodges the cavernous sinus, the internal carotid artery, and the nerves of the orbit. The sides of the middle fossa are of considerable depth; they present eminences and depressions for the convolutions of the brain and grooves for the branches of the middle meningeal artery; the latter commence on the outer side of the foramen spinosum, and consist of two large branches, an anterior and a posterior; the former passing upward and forward to the anterior inferior angle of the parietal bone, the latter passing upward and backward. The following foramina may also be seen from before backward: Most anteriorly is the \textit{foramen lacerum anterius}, or \textit{sphenoidal fissure}, formed above by the lesser wing of the sphenoid; below, by the greater wing; internally, by the body of the sphenoid; and sometimes completed externally by the orbital plate of the frontal bone. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery to the dura mater, and the ophthalmic vein. Behind the inner extremity of the sphenoidal fissure is the \textit{foramen rotundum}, for the passage of the second division of the fifth or superior maxillary nerve; still more posteriorly is seen a small orifice, the \textit{foramen Vesali}, an opening situated between the foramen rotundum and ovale, a little internal to both: it varies in size in different individuals, and is often absent; when present, it transmits a small vein. It opens below into the pterygoid fossa, just at the outer side of the sphenoid depression. Behind and external to the latter opening is the \textit{foramen ovale}, which transmits the third division of the fifth or inferior maxillary nerve, the small meningeal artery, and the small petrosal nerve.\footnote{\textit{See footnote, p. 182.}} On the outer side of the foramen ovale is the \textit{foramen spinosum}, for the passage of the middle meningeal artery; and
THE BASE OF THE SKULL.

on the inner side of the foramen ovale, the foramen lacerum medium. This aperture is filled up with fibrous tissue in the recent state. The Vidian nerve and a meningeal branch from the ascending pharyngeal artery pierce this cartilage. On the anterior surface of the petrous portion of the temporal bone is seen, from without inward, the eminence caused by the projection of the superior semicircular canal; outside this a depression corresponding to the roof of the tympanum; the groove leading to the hiatus Fallopii, for the transmission of the petrosal branch of the Vidian nerve and the petrosal branch of the middle meningeal artery; beneath it, the smaller groove, for the passage of the lesser petrosal nerve; and, near the apex of the bone, the depression for the Gasserian ganglion; and the orifice of the carotid canal, for the passage of the internal carotid artery and carotid plexus of nerves.

The Posterior Fossa, deeply concave, is the largest of the three, and situated on a lower level than either of the preceding. It is formed by the posterior third of the superior surface of the body of the sphenoid, by the occipital, the petrous and mastoid portions of the temporal, and the posterior inferior angle of the parietal bone; it is crossed by four sutures, the petro-occipital, the masto-occipital, the masto-parietal, and the basilar; and lodges the cerebellum, pons Varolii, and medulla oblongata. It is separated from the middle fossa in the median line by the dorsum episphii, and on each side by the superior border of the petrous portion of the temporal bone. This border serves for the attachment of the tentorium cerebelli, is grooved for the superior petrosal sinus, and at its inner extremity presents a notch, upon which rests the fifth nerve. The circumference of the fossa is bounded posteriorly by the grooves for the lateral sinuses. In the centre of this fossa is the foramen magnum, bounded on either side by a rough tubercle, which gives attachment to the odontoid or check ligaments; and a little above these are seen the internal openings of the anterior condylid foramina, through which pass the hypoglossal nerve, and a meningeal branch from the ascending pharyngeal artery. In front of the foramen magnum is a grooved surface, formed by the basilar process of the occipital bone and by the posterior third of the superior surface of the body of the sphenoid, which supports the medulla oblongata and pons Varolii, and articulates on each side with the petrous portion of the temporal bone, forming the petro-occipital suture, the anterior half of which is grooved for the inferior petrosal sinus, the posterior half being encroached upon by the foramen lacerum posteiui, or jugular foramen. This foramen presents three compartments: through the anterior passes the inferior petrosal sinus; through the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and through the middle, the glossopharyngeal, pneumogastric, and spinal accessory nerves. Above the jugular foramen is the internal auditory meatus, for the facial and auditory nerves and auditory artery; behind and external to this is the slit-like opening leading into the aqueductus vestibuli; whilst between the two latter, and near the superior border of the petrous portion, is a small, triangular depression which lodges a process of the dura mater and occasionally transmits a small vein into the substance of the bone. Behind the foramen magnum are the inferior occipital fossae, which lodge the hemispheres of the cerebellum, separated from one another by the internal occipital crest, which serves for the attachment of the falx cerebelli and lodges the occipital sinus. The posterior fossae are surmounted, above, by the deep transverse grooves for the lodgment of the lateral sinuses. These channels, in their passage outward, groove the occipital bone, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and terminate at the back part of the jugular foramen. Where this sinus grooves the mastoid portion of the temporal bone the orifice of the mastoid foramen may be seen, and just previous to its termination it has opening into it the posterior condylid foramen. Neither foramen is constant.

The External Surface of the Base of the Skull (Fig. 173) is extremely irregular. It is bounded in front by the incisor teeth in the upper jaws; behind by the
superior curved lines of the occipital bone; and laterally by the alveolar arch, the lower border of the malar bone, the zygoma, and an imaginary line extending from the zygoma to the mastoid process and extremity of the superior curved line
of the occiput. It is formed by the palate processes of the superior maxillary and palate bones, the vomer, the pterygoid processes, under surface of the great wing, spinous processes and part of the body of the sphenoid, the under surface of the squamous, mastoid, and petrous portions of the temporal, and the under surface of the occipital bone. The anterior part of the base of the skull is raised above the level of the rest of this surface (when the skull is turned over for the purpose of examination), surrounded by the alveolar process, which is thicker behind than in front, and excavated by sixteen depressions for lodging the teeth of the upper jaw, the cavities varying in depth and size according to the teeth they contain. Immediately behind the incisor teeth is the anterior palatine fossa. At the bottom of this fossa may usually be seen four apertures: two placed laterally, the foramina of Stenson, which open above, one in the floor of each nostril, and transmit the anterior branch of the posterior palatine vessels, and two in the median line in the intermaxillary suture, the foramina of Scorpa, one in front of the other, the anterior transmitting the left, and the posterior (the larger) the right, naso-palatine nerve. These two latter canals are sometimes wanting, or they may join to form a single one, or one of them may open into one of the lateral canals above referred to. The palatine vault is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and crossed by a crucial suture, formed by the junction of the four bones of which it is composed. At the front part of this surface a delicate linear suture may frequently be seen, marking off the pre-maxillary portion of the bone. One or two small foramina in the alveolar margin behind the incisor teeth, occasionally seen in the adult, almost constantly in young subjects, are called the incisive foramina; they transmit nerves and vessels to the incisor teeth. At each posterior angle of the hard palate is the posterior palatine foramen, for the transmission of the posterior palatine vessels and large descending palatine nerve; and running forward and inward from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the tuberosity of the palate bone, perforated by one or more accessory posterior palatine canals, and marked by the commencement of a ridge, which runs transversely inward, and serves for the attachment of the tendinous expansion of the Tensor palati muscle. Projecting backward from the centre of the posterior border of the hard palate is the posterior nasal spine, for the attachment of the Azygos uvulae. Behind and above the hard palate is the posterior aperture of the nares, divided into two parts by the vomer, bounded above by the body of the sphenoid, below by the horizontal plate of the palate bone, and laterally by the pterygoid processes of the sphenoid. Each aperture measures about an inch and a quarter in the vertical and about half an inch in the transverse direction. At the base of the vomer may be seen the expanded ale of this bone, receiving between them the rostrum of the sphenoid. Near the lateral margins of the vomer, at the root of the pterygoid processes, are the pterygo-palatine canals. The pterygoid process, which bounds the posterior nares on each side, presents near its base the pterygoid or Vidian canal, for the Vidian nerve and artery. Each process consists of two plates, which bifurcate at the extremity to receive the tuberosity of the palate bone, and are separated behind by the pterygoid fossa, which lodges the Internal pterygoid muscle. The internal plate is long and narrow, presenting on the outer side of its base the sphenoid fossa, for the origin of the Tensor palati muscle, and at its extremity the hamular process, around which the tendon of this muscle turns. The external pterygoid plate is broad, forms the inner boundary of the zygomatic fossa, and affords attachment by its outer surface to the External pterygoid muscle. Behind the nasal fosse in the middle line is the basilar surface of the occipital bone, presenting in its centre the pharyngeal spine, for the attachment of the Superior constrictor muscle of the pharynx, with depressions on each side for the insertion of the Rectus capitis anticus major and minor. At the base of the external pterygoid plate is the foramen ovale; behind this, the foramen spinosum and the prominent spinous process of the sphenoid, which gives attachment to the internal lateral ligament of the lower jaw and the Tensor palati muscle. External
to the spinous process is the *glenoid fossa*, divided into two parts by the Glaserian fissure (page 176), the anterior portion concave, smooth, bounded in front by the eminentia articularis, and serving for the articulation of the condyle of the lower jaw; the posterior portion rough, bounded behind by the tympanic plate, and serving for the reception of part of the parotid gland. Emerging from between the laminae of the vaginal process of the tympanic plate is the *styloid process*, and at the base of this process is the *stylo-mastoid foramen*, for the exit of the facial nerve and entrance of the stylo-mastoid artery. External to the stylo-mastoid foramen is the *auricular fissure*, for the auricular branch of the pneumogastric, bounded behind by the mastoid process. Upon the inner side of the mastoid process is a deep groove, the *digastric fossa*; and a little more internally the *occipital groove*, for the occipital artery. At the base of the internal pterygoid plate is a large and somewhat triangular aperture, the *foramen lacerum medium*, bounded in front by the great wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and internally by the body of the sphenoid and basilar process of the occipital bone: it presents in front the posterior orifice of the Vidian canal; behind, the aperture of the carotid canal. The basilar surface of this opening is filled up in the recent state by fibrous tissue; across its upper or cerebral aspect pass the internal carotid artery and Vidian nerve. External to this aperture the *petro-sphenoidal suture* is observed, at the outer termination of which is seen the orifice of the canal for the Eustachian tube and that for the Tensor tympani muscle. Behind this suture is seen the under surface of the petrous portion of the temporal bone, presenting, from within outward the quadrilateral, rough surface, part of which affords attachment to the Levator palati and Tensor tympani muscles; external to this surface the orifices of the carotid canal and the aque ductus cochleae, the former transmitting the internal carotid artery and the ascending branches of the superior cervical ganglion of the sympathetic, the latter serving for the passage of a small artery and vein to the cochlea. Behind the carotid canal is a large aperture, the *jugular fossa*, formed in front by the petrous portion of the temporal, and behind by the occipital; it is generally larger on the right than on the left side, and is divided into three compartments by processes of dura mater. The anterior is for the passage of the inferior petrosal sinus; the posterior, for the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; the central one, for the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the ridge of bone dividing the carotid canal from the jugular fossa is the small foramen for the transmission of Jacobson’s nerve; and on the outer wall of the jugular foramen, near the root of the styloid process, is the small aperture for the transmission of Arnold’s nerve. Behind the basilar surface of the occipital bone is the *foramen magnum*, bounded on each side by the condyles, rough internally for the attachment of the cheek or odontoid ligaments, and presenting externally a rough surface, the *jugular process*, which serves for the attachment of the Rectus capitis lateralis muscle and the lateral occipito-atlantal ligament. On either side of each condyle anteriorly is the *anterior condyloid fossa*, perforated by the anterior condyloid foramen, for the passage of the hypoglossal nerve and a meningeal artery. Behind each condyle is the *posterior condyloid fossa*, perforated on one or both sides by the posterior condyloid foramina, for the transmission of a vein to the lateral sinus. Behind the foramen magnum is the *external occipital crest*, terminating above at the *external occipital protuberance*, whilst on each side are seen the *superior and inferior curved lines*; these, as well as the surfaces of bone between them, are rough for the attachment of the muscles, which are enumerated on page 168.

**The Lateral Region of the Skull.**

The Lateral Region of the Skull is of a somewhat triangular form, the base of the triangle being formed by a line extending from the external angular process of the frontal bone along the temporal ridge backward to the outer extremity of
the superior curved line of the occiput: and the sides by two lines, the one drawn downward and backward from the external angular process of the frontal bone to the angle of the lower jaw, the other from the angle of the jaw upward and

backward to the outer extremity of the superior curved line. This region is divisible into three portions—temporal fossa, mastoid portion, and zygomatic fossa.

**The Temporal Fossa.**

The **Temporal Fossa** is bounded above and behind by the temporal ridge, which extends from the external angular process of the frontal upward and backward across the frontal and parietal bones, curving downward behind to terminate in the posterior root of the zygomatic process. This ridge is generally double—at all events in front, where it is most marked. In front it is bounded by the frontal, malar, and great wing of the sphenoid; externally by the zygomatic arch formed conjointly by the malar and temporal bones; below it is separated from the zygomatic fossa by the pterygoid ridge, seen on the outer surface of the great wing of the sphenoid. This fossa is formed by five bones, part of the frontal, great wing of the sphenoid, parietal, squamous portion of the temporal, and malar bones, and is traversed by six sutures, part of the transverse facial, sphenomalar, coronal, sphenoparietal, squamo-parietal, and squamo-sphenoidal. The point where the coronal suture crosses the temporal ridge is sometimes named the *steplanion*; and the region where the four bones, the parietal, the frontal, the squamous, and the greater wing of the sphenoid, meet, at the anterior inferior angle of the parietal bone, is named the *pterion*. This point is about on a level with the
external angular process of the frontal bone and about one and a half inches behind it. This fossa is deeply concave in front, convex behind, traversed by grooves which lodge branches of the deep temporal arteries, and filled by the Temporal muscles.

The Mastoid Portion.

The **Mastoid Portion** of the side of the skull is bounded in front by the tubercle of the zygoma; above, by a line which runs from the posterior root of the zygoma to the end of the masto-parietal suture; behind and below by the masto-occipital suture. It is formed by the mastoid and part of the squamous and petrous portions of the temporal bone; its surface is convex and rough for the attachment of muscles, and presents, from behind forward, the mastoid foramen, the mastoid process, the external auditory meatus surrounded by the auditory process, and, most anteriorly, the temporo-maxillary articulation.

The Zygomatic Fossa.

The **Zygomatic Fossa** is an irregularly shaped cavity, situated below and on the inner side of the zygoma; bounded, in front, by the tuberosity of the superior maxillary bone and the ridge which descends from its malar process; behind, by the posterior border of the pterygoid process and the eminentia articularis; above, by the pterygoid ridge on the outer surface of the great wing of the sphenoid and the under part of the squamous portion of the temporal; below, by the alveolar border of the superior maxilla; internally, by the external pterygoid plate; and externally, by the zygomatic arch and ramus of the lower jaw. It contains the lower part of the Temporal, the External and Internal pterygoid muscles, the internal maxillary artery, and inferior maxillary nerve and their branches. At its upper and inner part may be observed two fissures, the spheno-maxillary and pterygo-maxillary.

The **Spheno-maxillary Fissure**, horizontal in direction, opens into the outer and back part of the orbit. It is formed above by the lower border of the orbital surface of the great wing of the sphenoid; below, by the external border of the orbital surface of the superior maxilla and a small part of the palate bone; externally, by a small part of the malar bone; \(^1\) internally, it joins at right angles with the pterygo-maxillary fissure. This fissure opens a communication from the orbit into three fossae—the temporal, zygomatic, and spheno-maxillary; it transmits the superior maxillary nerve and its orbital branch, the infraorbital vessels, and ascending branches from the sphenopalatine or Meckel's ganglion.

The **Pterygo-maxillary Fissure** is vertical, and descends at right angles from the inner extremity of the preceding; it is a V-shaped interval, formed by the divergence of the superior maxillary bone from the pterygoid process of the sphenoid. It serves to connect the spheno-maxillary fossa with the zygomatic fossa, and transmits branches of the internal maxillary artery. It forms the entrance from the zygomatic fossa to the spheno-maxillary fossa.

The **Spheno-maxillary Fossa** is a small, triangular space situated at the angle of junction of the spheno-maxillary and pterygo-maxillary fissures, and placed beneath the apex of the orbit. It is formed above by the under surface of the body of the sphenoid and by the orbital process of the palate bone; in front, by the superior maxillary bone; below, by the anterior surface of the base of the pterygoid process and lower part of the anterior surface of the great wing of the sphenoid; internally, by the vertical plate of the palate. This fossa has three fissures terminating in it—the *sphenoidal*, *spheno-maxillary*, and *pterygo-maxillary*; it communicates with three fossae, the *orbital*, *nasal*, and *zygomatic*, and with the cavity of the cranium, and has opening into it five foramina. Of these, there are

---

\(^1\) Occasionally the superior maxillary bone and the sphenoid articulate with each other at the anterior extremity of this fissure; the malar is then excluded from entering into its formation.
three on the posterior wall; the *foramen rotundum* above; below and internal to this, the *Vidian*; and still more inferiorly and internally, the *pterygo-palatine*. On the inner wall is the *sphenopatine foramen*, by which the sphenoid-maxillary communicates with the nasal fossa; and below is the superior orifice of the *posterior palatine canal*, besides occasionally the orifices of the *accessory posterior palatine* canals. The fossa contains the superior maxillary nerve and Meckel's ganglion, and the termination of the internal maxillary artery.

### The Anterior Region of the Skull.

The *Anterior Region* of the Skull, which forms the face, is of an oval form, presents an irregular surface, and is excavated for the reception of two of the organs of sense, the eye and the nose. It is bounded above by the glabella and margins of the orbit; below, by the prominence of the chin; on each side by the malar bone and anterior margin of the ramus of the jaw. In the median line are seen from above downward the glabella, and diverging from it are the *superciliary ridges*, which indicate the situation of the frontal sinuses and support the eyebrows. Beneath the glabella is the fronto-nasal suture, the mid-point of which is termed the *nasion*, and below this is the arch of the nose, formed by the nasal bones, and the nasal processes of the superior maxillary. The nasal arch is convex from side to side, concave from above downward, presenting in the median line the inter-nasal suture formed between the nasal bones, laterally the naso-maxillary suture formed between the nasal bone and the nasal process of the superior maxillary bone. Below the nose is seen the opening of the anterior nares, which is heart-shaped, with the narrow end upward, and presents laterally the thin, sharp margins serving for the attachment of the lateral cartilages of the nose, and in the middle line below a prominent process, the *anterior nasal spine*, bounded by two deep notches. Below this is the *internasal suture*, and on each side of it the *incisive fossa*. Beneath this fossa are the alveolar processes of the upper and lower jaws, containing the incisor teeth, and at the lower part of the median line the *symphysis of the chin*, the *mental process*, with its two *mental tubercles*, separated by a median groove, and the *incisive fossa* of the lower jaw.

On each side, proceeding from above downward, is the *supraorbital ridge*, terminating externally in the external angular process at its junction with the malar, and internally in the internal angular process; toward the inner third of this ridge is the *supraorbital notch* or *foramen*, for the passage of the supraorbital vessels and nerve, and at its inner side a slight depression, for the attachment of the pulley of the Superior oblique muscle. Beneath the supraorbital ridge is the opening of the orbit, bounded externally by the orbital ridge of the malar bone; below, by the orbital ridge formed by the malar and nasal process of superior maxillary; internally, by the nasal process of the superior maxillary and the internal angular process of the frontal bone. On the outer side of the orbit is the quadrilateral anterior surface of the malar bone, perforated by one or two small malar foramina. Below the inferior margin of the orbit is the *infraorbital foramen*, the termination of the infraorbital canal, and beneath this the *canine fossa*, which gives attachment to the Levator anguli oris; bounded below by the alveolar processes, containing the teeth of the upper and lower jaws. Beneath the alveolar arch of the lower jaw is the *mental foramen*, for the passage of the mental vessels and nerve, the *external oblique line*, and at the lower border of the bone, at the point of junction of the body with the ramus, a shallow groove for the passage of the facial artery.

### The Orbits.

The *Orbits* (Fig. 175) are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forward and outward, and their apices backward and inward, so that the axes of the two, if continued backward, would meet over the body of the sphenoid bone. Each orbit is formed of *seven* bones, the frontal, sphenoid, ethmoid, superior maxillary, malar,
lachrymal, and palate; but three of these, the frontal, ethmoid, and sphenoid, enter into the formation of both orbits, so that the two cavities are formed of eleven bones only. Each cavity presents for examination a roof, a floor, an inner and an outer wall, four angles, a circumference or base, and an apex. The roof is concave, directed downward and forward, and formed in front by the orbital plate of the frontal; behind by the lesser wing of the sphenoid. This surface presents internally the depression for the cartilaginous pulley of the Superior oblique muscle; externally, the depression for the lachrymal gland; and posteriorly, the suture connecting the frontal and lesser wing of the sphenoid.

The floor is nearly flat, and of less extent than the roof; it is formed chiefly by the orbital surface of the superior maxillary; in front, to a small extent, by the orbital process of the malar, and behind, by the superior surface of the orbital process of the palate. This surface presents at its anterior and internal part, just external to the lachrymal groove, a depression for the attachment of the Inferior oblique muscle; externally, the suture between the malar and superior maxillary bones; near its middle, the infraorbital groove; and posteriorly, the suture between the maxillary and palate bones.

The inner wall is flattened, and formed from before backward by the nasal process of the superior maxillary, the lachrymal, os planum of the ethmoid, and a small part of the body of the sphenoid. This surface presents the lachrymal groove and crest of the lachrymal bone, and the sutures connecting the lachrymal
with the superior maxillary, the ethmoid with the lachrymal in front, and the ethmoid with the sphenoid behind.

The outer wall is formed in front by the orbital process of the malar bone; behind, by the orbital surface of the sphenoid. On it are seen the orifices of one or two malar canals, and the suture connecting the sphenoid and malar bones.

Angles.—The superior external angle is formed by the junction of the upper and outer walls; it presents, from before backward, the suture connecting the frontal with the malar in front and with the great wing of the sphenoid behind; quite posteriorly is the foramen lacerum anterius, or sphenoidal fissure, which transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The superior internal angle is formed by the junction of the upper and inner wall, and presents the suture connecting the frontal bone with the lachrymal in front and with the ethmoid behind. The point of junction of these three sutures has been named the dacryon. This angle presents two foramina, the anterior and posterior ethmoidal, the former transmitting the anterior ethmoidal vessels and nasal nerve, the latter the posterior ethmoidal vessels. The inferior external angle, formed by the junction of the outer wall and floor, presents the sphen-maxillary fissure, which transmits the superior maxillary nerve and its orbital branches, the infraorbital vessels, and the ascending branches from the sphenopalatine or Meckel’s ganglion. The inferior internal angle is formed by the union of the lachrymal and os planum of the ethmoid with the superior maxillary and palatine bones.

The circumference, or base, of the orbit, quadrilateral in form, is bounded above by the supraorbital ridge; below, by the anterior border of the orbital plate of the malar, superior maxillary, and its nasal process; externally, by the external angular process of the frontal and the malar bones; internally, by the internal angular process of the frontal and the nasal process of the superior maxillary. The circumference is marked by three sutures, the fronto-maxillary internally, the fron-to-malar externally, and the malo-maxillary below; it contributes to the formation of the lachrymal groove, and presents, above, the supraorbital notch (or foramen), for the passage of the supraorbital vessels and nerve. The apex, situated at the back of the orbit, corresponds to the optic foramen, a short, circular canal, which transmits the optic nerve and ophthalmic artery. It will thus be seen that there are nine openings communicating with each orbit—viz. the optic foramen, foramen lacerum anterius, sphen-maxillary fissure, supraorbital foramen, infraorbital canal, anterior and posterior ethmoidal foramina, malar foramina, and canal for the nasal duct.

The Nasal Fossae.

The Nasal Fossae are two large, irregular cavities situated on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum. They communicate by two large apertures, the anterior nares, with the front of the face, and by the two posterior nares with the pharynx behind. These fossae are much narrower above than below, and in the middle than at the anterior or posterior openings; their depth, which is considerable, is much greater in the middle than at either extremity. Each nasal fossa communicates with four sinuses, the frontal above, the sphenoidal behind, and the maxillary and ethmoidal on the outer wall. Each fossa also communicates with four cavities: with the orbit by the lachrymal groove, with the mouth by the anterior palatine canal, with the cranium by the olfactory foramina, and with the sphen-maxillary fossa by the sphen-opalatine foramen; and they occasionally communicate with each other by an aperture in the septum. The bones entering into their formation are fourteen in number: three of the cranium, the frontal, sphenoid, and ethmoid, and all the bones of the
face, excepting the malar and lower jaw. Each cavity is bounded by a roof, a floor, an inner and an outer wall.

The upper wall, or roof (Fig. 176), is formed in front by the nasal bones and groove lateral to the nasal spine of the frontal; this part is directed downward and forward; in the middle, by the cribiform plate of the ethmoid, which is horizontal; and behind, by the under surface of the body of the sphenoid, sphenoidal process of the palate bone, and ala of the vomer, which are directed downward and backward. This surface presents, from before backward, the internal aspect of the nasal bones; on their outer side, the suture formed between the nasal bone and the nasal process of the superior maxillary; on their inner side, the elevated crest which receives the nasal spine of the frontal and the perpendicular plate of the ethmoid, and articulates with its fellow of the opposite side; whilst the surface of the bones is perforated by a few small vascular apertures, and presents the longitudinal groove for the nasal nerve; farther back is the transverse suture, connecting the frontal with the nasal in front, and the ethmoid behind, the olfactory foramina and nasal slit on the under surface of the cribiform plate, and the suture between it and the sphenoid behind; quite posteriorly are seen the sphenoidal turbinate bones, the orifices of the sphenoidal sinuses, and the articulation of the alae of the vomer with the under surface of the body of the sphenoid.

The floor is flattened from before backward, concave from side to side, and wider in the middle than at either extremity. It is formed in front by the palate process of the superior maxillary; behind, by the palate process of the palate bone. This surface presents, from before backward, the anterior nasal spine; behind this, the upper orifices of the anterior palatine canal; internally, the elevated crest which articulates with the vomer; and behind, the suture between the palate and superior maxillary bones, and the posterior nasal spine.

The inner wall, or septum (Fig. 177), is a thin vertical partition which separates the nasal fosse from one another; it is occasionally perforated, so that the
fossae communicate, and it is often bent considerably to one side. It is formed, in front, by the crest of the nasal bones and nasal spine of the frontal; in the middle, by the perpendicular plate of the ethmoid; behind, by the vomer, rostrum and ethmoidal crest of the sphenoid; below, by the crests of the superior maxillary and palatine bones. It presents, in front, a large, triangular notch, which receives the triangular cartilage of the nose; and behind, the guttural edge of the vomer. Its surface is marked by numerous vascular and nervous canals and the groove for the naso-palatine nerve, and is traversed by sutures connecting the bones of which it is formed.

The outer wall (Fig. 176) is formed, in front, by the nasal, the nasal process of the superior maxillary and lachrymal, bones; in the middle, by the ethmoid and inner surface of the superior maxillary and inferior turbinate bones; behind, by the vertical plate of the palate bone and the internal pterygoid plate of the sphenoid. This surface presents three irregular longitudinal passages, or meatuses, formed between three plates of bone that spring from it; they are termed the superior, middle, and inferior meatuses of the nose. The superior meatus, the smallest of the three, is situated at the upper and back part of each nasal fossa, occupying the posterior third of the outer wall. It is situated between the superior and middle turbinate bones, and has opening into it two foramina, the spheno-palatine at the back of its outer wall, and the posterior ethmoidal cells at the front part of the outer wall. The opening of the sphenoidal sinus is at the upper and back part of the nasal fossa immediately behind the superior turbinate bone and into a groove, the spheno-ethmoidal recess. The middle meatus is situated between the middle and inferior turbinate bones, and occupies the posterior two-thirds of the outer wall of the nasal fossa. It has two apertures: in front that of the infundibulum, by which the meatus communicates with the anterior ethmoidal cells, and through these with the frontal sinuses; near the centre is the orifice of the antrum, which varies somewhat as to its exact position in different skulls. The inferior meatus, the largest of the three, is the space between the inferior turbinate

---

1 See footnote, p. 185.
bone and the floor of the nasal fossa. It extends along the entire length of the outer wall of the nose, is broader in front than behind, and presents anteriorly the lower orifice of the canal for the nasal duct.

The anterior nares present a heart-shaped or pyriform opening whose long axis is vertical and narrow extremity upward. This opening in the recent state is much contracted by the cartilages of the nose. It is bounded above by the inferior border of the nasal bone; laterally by the thin, sharp margin which separates the facial from the nasal surface of the superior maxillary bone; and below by the same border, where it slopes inward to join its fellow of the opposite side at the anterior nasal spine.

The posterior nares are the two posterior oval openings of the nasal fosse, by which they communicate with the upper part of the pharynx. They are situated immediately in front of the basal process, and are bounded above by the under surface of the body of the sphenoid; below by the posterior border of the horizontal plate of the palatine bone; externally, by the internal surface of the internal pterygoid plate; and internally, in the middle line, they are separated from each other by the guttural border of the vomer.

Surface Form.—The various bony prominences or landmarks which are to be easily felt and recognized in the head and face, and which afford the means of mapping out the important structures comprised in this region, are as follows:

2. Internal angular process. 9. Temporal ridge.
4. Zygomatic arch. 11. Superciliary ridges.

1. The supraorbital arches are to be felt throughout their entire extent, covered by the eyebrows. They form the upper boundary of the circumference or base of the orbit, and separate the face from the forehead. They are strong and arched, and terminate internally on each side of the root of the nose in the internal angular process, which articulates with the lacrimal bone. Externally they terminate in the external angular process, which articulates with the malar bone. This arched ridge is sharper and more defined in its outer than in its inner half, and forms an overhanging process which protects and shields the lacrimal gland. It thus protects the eye in its most exposed situation and in the direction from which blows are most likely to descend. The supraorbital arch varies in prominence in different individuals. It is more marked in the male than in the female, and in some races of mankind than others. In the less civilized races, as the forehead recedes backward, the supraorbital arch becomes more prominent, and approaches more to the characters of the monkey tribe, in which the supraorbital arches are very largely developed, and acquire additional prominence from the oblique direction of the frontal bone. 2. The internal angular process is scarcely to be felt. Its position is indicated by the angle formed by the supraorbital arch with the nasal process of the superior maxillary bone and the lacrimal bone at the inner side of the orbit. Between the internal angular processes of the two sides is a broad surface which assists in forming the root of the nose, and immediately above this a broad, smooth, somewhat triangular surface, the glabella, situated between the superciliary ridges. 3. The external angular process is much more strongly marked than the internal, and is plainly to be felt. It is formed by the junction or confluence of the supraorbital and temporal ridges, and, articulating with the malar bone, it serves to a very considerable extent to support the bones of the face. In carnivorous animals the external angular process does not articulate with the malar, and therefore this lateral support to the bones of the face is not present. 4. The zygomatic arch is plainly to be felt throughout its entire length, being situated almost immediately under the skin. It is formed by the malar bone and the zygomatic process of the temporal bone. At its anterior extremity, where it is formed by the malar bone, it is broad and forms the prominence of the cheek; the posterior part is narrower, and terminates just in front and a little above the tragus of the external ear. The lower border is more plainly to be felt than the upper, in consequence of the dense temporal fascia being attached to the upper border, which somewhat obscures its outline. Its shape differs very much in individuals and in different races of mankind. In the most degraded type of skull—as, for instance, in the skull of the negro of the Guinea Coast—the malar bones project forward and not outward, and the zygoma at its posterior extremity extends farther outward before it is twisted on itself to be prolonged forward. This makes the zygomatic arch stand out in bold relief, and affords greater space for the Temporal muscle. In skulls which have a more pyramidal shape, as in the Esquimaux or Greenlanders, the malar bones do not project forward and downward under the eyes, as in the preceding form, but take a direction outward, forming with the zygoma a large, rounded sweep or segment of a circle. Thus it happens that if two lines are drawn from the
zygomatic arches, touching the temporal ridges, they meet over the top of the head, instead of being parallel, or nearly so, as in the European skull, in which the zygomatic arches are not nearly so prominent. This gives to the face a more or less oval type. 5. Behind the ear is the mastoid portion of the temporal bone, plainly to be felt, and terminating below in a nippleshaped process. Its anterior border can be traced immediately behind the concha, and its apex is on about a level with the lobule of the ear. It is rudimentary in infancy, but gradually develops in childhood, and is more marked in the negro than in the European. 6. The external occipital protuberance is also a plainly to be felt just at the level where the skin of the occiput meets that of the head. At this point the skull is thick for the purposes of safety, while radiating from it are numerous curved arches or buttresses of bone which give to this portion of the skull further security. 7. Running outward on either side from the external occipital protuberance is an arched ridge of bone, which can be more or less plainly perceived. This is the superior curve of the occipital bone, and gives attachment to some of the muscles which keep the head erect on the spine; accordingly, we find it more developed in the negro tribes, in whom the jaws are much more massive, and therefore require stronger muscles to prevent their extra weight carrying the head forward. Below this line the surface of bone at the back of the head is obscured by the overlying muscles. Above it, the vault of the cranium is thinly covered with soft structures, so that the form of this part of the head is almost exactly that of the upper portion of the occipital bone, the front of the frontal bones themselves; and in bald persons even the lines of junction of the bones, especially the junction of the occipital and parietal at the lambdoid suture, may be defined as a slight depression, caused by the thickening of the borders of the bones in this situation. 8. In the line of the greatest transverse diameter of the head, on each side of the middle line, are generally to be found the parietal eminences, though sometimes these eminences are not situated at the point of the greatest transverse diameter, which is at some other prominent part of the parietal region. They denote the point where ossification of the bone began. They are much more prominent and well-marked in early life, in consequence of the sharper curve of the bone at this period, so that it describes the segment of a smaller circle. Later in life, as the bone grows, the curve spreads out and forms the eminence which becomes less distinctly marked. The prominence of this sharp curve of the bone in early life, the whole of the vault of the skull has a squarer shape than it has in later life, and this appearance may persist in some rickety skulls. The eminence is more apparent in the negro's skull than in that of the European. This is due to greater flattening of the temporal fossa, the former skull to accommodate the larger temporal muscle which exists in these races. The parietal eminence is particularly exposed to injury from blows or falls on the head, but fracture is to a certain extent prevented by the shape of the bone, which forms an arch, so that the force of the blow is diffused over the bone in every direction. 9. At the side of the head may be felt the temporal ridge. Commencing at the external angular process, it may be felt as a curved ridge, passing upward and then curving backward, on the frontal bone, separating the forehead from the temporal fossa. It may then be traced, passing backward in a curved direction, over the frontal bone, and, though less marked, still generally to be recognized. Finally, the ridge curves downward, and terminates in the posterior root of the zygoma, which separates the squamous from the subcutaneous mastoid portion of the temporal bone. Mr. Victor Horsley has recently shown, in an article on the "Topography of the Cerebral Cortex," that the second temporal ridge (see page 170) can be made out on the living body. 10. The frontal eminences vary a good deal in different individuals, being considerably more prominent in some than in others, and they are often not symmetrical on the two sides of the body, the one being much more pronounced than the other. This is often especially noticeable in the skull of the young child or infant, and becomes less marked as age advances. The prominence of the frontal eminences depends more upon the general shape of the frontal bone than upon the size of the protuberances themselves. As the skull is more highly developed in consequence of increased intellectual capacity, so the frontal bone becomes more upright and the frontal eminences stand out in bolder relief. Thus they may be considered as owing, to a certain extent, an indication of the development of the hemispheres of the brain beneath, and of the mental powers of the individual. They are not so much exposed to injury as the parietal eminences. In falls forward the upper extremities are involuntarily thrown out, and break the force of the fall, and thus shield the frontal bone from injury. 11. Below the frontal eminences on the forehead are the superciliary ridges, which denote the position of the frontal sinuses, and vary according to the size of the sinuses in different individuals, being, as a rule, small in the female, absent in children, and sometimes unusually prominent in the male, when the frontal sinuses are largely developed. They commence on either side of the glabella, and at first present a rounded form, which gradually fades away at their outer ends. 12. The nasal bones form the prominence of the nose. They vary much in size and shape, and to them is due the variety in the contour of this organ and much of the character of the face. Thus, in the Mongolian or Ethiopian they are flat, broad and thick at their base, giving to these tribes the flattened nose by which they are characterized, and differing very decidedly from the Caucasian, in whom the nose, owing to the shape of the nasal bones, is narrow, elevated at the bridge, and elongated downward. Below, the nasal bones are thin and connected with the cartilages of the nose, and the angle or arch formed by their union serves to throw out the bridge of the nose, and is much more marked in some individuals than others. 13. The lower margin of the orbit, formed by the superior maxillary bone and the malar bone, is plainly to be felt throughout its entire length. It is continuous internally with the nasal process of the superior
THE SKELETON.

maxillary bone, which forms the inner boundary of the orbit. At the point of junction of the lower margin of the orbit with the nasal process is to be felt a little tubercle of bone, which can be plainly perceived by running the finger along the bone in this situation. This tubercle serves as a guide to the position of the lacrymal sac, which is situated above and behind it. 14. The outline of the lower jaw is to be felt throughout its entire length. Just in front of the trigus of the external ear, and below the zygomatic arch, the condyle can be made out. When the mouth is opened this prominence of bone can be perceived advancing out of the glenoid fossa on to the eminencia articularis, and receding again when the mouth is closed. From the condyle the posterior border of the ramus can be felt extending down to the angle. A line drawn from the condyle to the angle would indicate the exact position of this border. From the angle to the symphysis chin the whole body of the bone is plainly to be felt. At the point of junction of the two halves of the bone is a well-marked triangular eminence, the mental process, which forms the prominence of the chin.

Surgical Anatomy.—An arrest in the ossifying process may give rise to deficiencies or gaps; or to fissures, which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margin toward the centre of the bone, but gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

Occasionally a protrusion of the brain or its membranes may take place through one of these gaps in an imperfectly developed skull. When the protrusion consists of membranes only, and is filled with cerebro-spinal fluid, it is called an arachnoid cyst. As well as membranes, it is termed an encephalocoele; and when the protruded brain is a prolongation from one of the ventricles, and is distended by a collection of fluid from an accumulation in the ventricle, it is termed an hydrocephalocoele. This latter condition is frequently found at the root of the nose, where a protrusion of the anterior horn of the lateral ventricle takes place through a deficiency of the fronto-nasal suture. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place through the fissures which separate the four centres of ossification from which the tabular portion is originally developed (see page 167). They most frequently occur through the upper part of the vertical fissure, which is the last to ossify; but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions have been met with in other situations than those above mentioned, both through normal fissures, as the sagittal, lambdoid, and other sutures, and also through abnormal gaps and deficiencies at the sides, and even at the base of the skull.

Fractures of the skull may be divided into those of the vault and those of the base. Fractures of the vault are usually produced by direct violence. This portion of the skull varies in thickness and strength in different individuals, but, as a rule, is sufficiently strong to resist a very considerable amount of violence without being fractured. This is due to several causes: the rounded shape of the head and its construction of a number of secondary elastic arches, each made up of a single bone; the fact that it consists of a number of bones, united, at all events in early life, by a sutural ligament, which acts as a sort of buffer and interrupts the continuity of any violence applied to the skull; the presence of arches or ridges, both on the inside and outside of the skull, which materially strengthen it; and the mobility of the head upon the spine which further enables it to withstand violence. The elasticity of the bones of the head is especially marked in the skull of the child, and this fact, together with the wide separation of the individual bones from each other, and the interposition between them of other softer structures renders fracture of the bones of the head a very uncommon event in infants and quite young children; as age advances and the bones become joined, fracture is more common, though still less liable to occur than in the adult. Fractures of the vault may, and generally do, involve the whole thickness of the bone; but sometimes one table may be fractured without any corresponding injury to the other. Thus, the outer table of the skull may be splintered and driven into the diploë, or in the frontal or mastoid regions into the frontal or mastoid cells, without any injury to the internal table. And on the other hand, the internal table has been fractured, and portions of it depressed and driven inward, without any fracture of the outer table. As a rule, in fractures of the skull the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inward becomes broken up, and is more diffused by the time it reaches the inner table; the bone, being in the form of an arch, bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch—i.e., the outer table—and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be simple fissures or starred and comminuted. In the first, these may be depressed and driven inward, as in fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if depressed, a fissure circumscribes the radiating line, enclosing a portion of skull. If this area is circular, it is termed a "pond" fracture, and would in all probability have been caused by a round instrument, as a life-preserver or hammer; if elliptical in shape, it is termed a "gutter fracture," and would owe its shape to the instrument which had produced it, as a poker.

Fractures of the base are most frequently produced by the extension of a fissure from the
vault, as in falls on the head, where the fissure starts from the part of the vault which first struck the ground. Sometimes, however, they are caused by direct violence, when foreign bodies have been forced through the thin roof of the orbit, through the cribiform plate of the ethmoid from being thrust up the nose, or through the roof of the pharynx. Other cases of fracture of the base occur from indirect violence, as in fracture of the occipital bone from impact of the spinal column against its condyles in falls on the buttocks, knees, or feet, or in cases where the glenoid cavity has been fractured by the violent impact of the condyle of the lower jaw against it from blows on the chin.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighborhood of the parietal eminence, it runs downward through the parietal and squamous portion of the temporal bone and across the petrosous portion of this bone, frequently traversing and implicating the internal auditory meatus, to the middle lacerated foramen. From this it may pass across the body of the sphenoid, through the pituitary fossa to the middle lacerated foramen of the other side, and may indeed travel round the whole cranium, so as to completely separate the anterior from the posterior part. The course of the fracture should be borne in mind, as it explains the symptoms to which fracture in this region may give rise; thus, if the fissure pass across the internal auditory meatus, injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn, and thus permit of the escape of the cerebro-spinal fluid should there be a communication between the internal ear and the tympanum and the membrana tympani be ruptured, as is frequently the case; again, if the fissure passes across the pituitary fossa and the muscularis peristemi covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal fossa, are generally the results of blows on the forehead, as from the fall of a horse, from the horse upon the rider's arm. It is, therefore, usually met with in the parietal and vertical plate of the occipital bone.

In congenital syphilis deposits of porous bone are often found at the angles of the parietal bones and two halves of the frontal bone which bound the anterior fontanelle. These deposits are separated by the coronal and sagittal sutures, and give to the skull an appearance like a "hot cross bun." They are known as Parrot's nodes, and such a skull has received the name of "nativiform." From its fancied resemblance to the buttocks.

In connection with the bones of the face a common malformation is clef palate, owing to the non-union of the palatal processes of the maxillary or pre-oral arch (see page 118). This cleft may involve the whole or only a portion of the hard palate, and usually involves the soft palate also. The cleft is in the middle line, except it involves the alveolus in front, when it follows the suture between the main portion of the bone and the pre-maxillary bone. Sometimes the cleft runs on either side of the pre-maxillary bone, so that this bone is quite isolated from the maxillary bones and hangs from the end of the vomer. The malformation is usually associated with hare-lip, which, when single, is almost always on one side, corresponding to the position of the suture between the lateral incisor and canine tooth. Some few cases of median hare-lip have been described. In double hare-lip there is a cleft on each side of the middle line.

The bones of the face are sometimes fractured as the result of direct violence. The two most commonly broken are the nasal bone and the inferior maxilla, and of these the latter is by far the most frequently fractured of all the bones of the face. Fracture of the nasal bone is for the most part transverse, and takes place about half an inch from the free margin. The broken portion may be displaced backward or more generally to one side by the force which produced the lesion, as there are no muscles here which can cause displacement. The malar bone is probably never broken alone; that is to say, unconnected with a fracture of the other bones of the face. The zygomatic arch is occasionally fractured, and when this occurs from
direct violence, as is usually the case, the fragments may be displaced inward. This lesion is often attended with great difficulty or even inability to open and shut the mouth, and this has been stated to be due to the depressed fragments perforating the temporal muscle, but would appear rather to be caused by the injury done to the bony origin of the Masseter muscle. Fractures of the superior maxilla may vary much in degree, from the chipping off of a portion of the alveolus to the complete severance of the bone. In this situation the coronoid process is often separated with the teeth for the extraction of teeth, to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the inferior maxillary bone is in the neighborhood of the canine tooth, as at this spot the jaw is weakened by the deep socket for the root of this tooth; it is next most frequently fractured at the angle; then at the symphysis, and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. The displacement is mainly the result of the same violence as produced the injury, but may be further increased by the action of the muscles passing from the neighborhood of the symphysis to the hyoid bone.

The superior and inferior maxillary bones are both of them frequently the seat of necrosis, though the disease affects the lower much more frequently than the upper jaw, probably on account of the greater supply of blood to the latter. It may be the result of periostitis, from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it not infrequently occurs in children after attacks of the exanthematic fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in match-making.

Tumors attack the jaw-bones not infrequently, and these may be either innocent or malignant: in the upper jaw cysts may occur in the antrum, constituting the so-called dropsy of the antrum; or, again, cysts may form in either jaw in connection with the teeth: either cysts connected with the roots of fully-developed teeth, the "dental cyst," or cysts connected with incompletely developed teeth, the SIEGUER cyst or "odontogenic cyst." These cysts may be of the chondroma, and the osteoma. Of malignant tumors there are two classes, the sarcomata and the epithelioma. The sarcoma are of various kinds, the spindle-celled and round-celled, of a very malignant character, and the myeloid sarcoma, principally affecting the alveolar margin of the bone. Of the epitheliomata we find the squamous variety spreading to the bone from the palate or gum, and the cylindrical epithelioma originating in the antrum or nasal fossae.

Both superior and inferior maxillary bones occasionally require removal for tumors and in some other conditions. The upper jaw is removed by an incision from the inner canthus of the eye, along the side of the nose, round the ala, and down the middle line of the upper lip. A second incision is carried outward from the inner canthus of the eye along the lower margin of the orbit as far as the prominence of the malar bone. The flap thus formed is reflected outward and the surface of the bone exposed. The connections of the bone to the other bones of the face are then divided with a narrow saw. They are (1) the junction with the malar bone, passing into the sphenoid-maxillary fissure; (2) the nasal process; a small portion of its upper extremity, connected with the nasal bone in front, the lacrymal bone behind, and the frontal bone above, being left; (3) the connection with the bone on the opposite side and the palate in the roof of the mouth. The bone is now firmly grasped with lion-forceps, and by means of a rocking movement upward and downward the remaining attachments of the orbital plate with the ethmoid, and the back of the bone with the palate, broken through. The soft palate is first separated from the hard with a scalpel, and is not removed. Occasionally in removing the upper jaw the upper margin of the plate is separated from the upper margin of the bone, as is always the case when the "bull eye" is sufficiently large, and the很想 finding its way into the cavity. The operation may be performed by incising the mucous membrane above the second molar tooth, and driving a trocar or any sharp-pointed instrument into the cavity.
THE HYOID BONE.

The Hyoid bone is named from its resemblance to the Greek upsilon; it is also called the lingual bone, because it supports the tongue and gives attachment to its numerous muscles. It is a bony arch, shaped like a horseshoe, and consisting of five segments, a body, two greater cornua, and two lesser cornua. It is suspended from the tip of the styloid processes of the temporal bone by ligamentous bands, the stylo-hyoid ligaments.

The Body (basi-hyal) forms the central part of the bone, and is of a quadrilateral form; its anterior surface (Fig. 178), convex, directed forward and upward, is divided into two parts by a vertical ridge which descends along the median line, and is crossed at right angles by a horizontal ridge, so that this surface is divided into four spaces or depressions. At the point of meeting of these two lines is a prominent elevation, the tubercle. The portion above the horizontal ridge is directed upward, and is sometimes described as the superior border. The anterior surface gives attachment to the Genio-hyoid in the greater part of its extent; above, to the Genio-hyo-glossus; below, to the Mylo-hyoid. Stylo-hyoid, and aponeurosis of the Digastric (suprahyoid aponeurosis); and between these to part of the Hyo-glossus. The posterior surface is smooth, concave, directed forward and downward, and separated from the epiglottis by the thyro-hyoid membrane and by a quantity of loose areolar tissue. The inferior border is rounded, and gives attachment to the thyro-hyoid membrane, part of the Genio-hyo-glossi and Chondro-glossi muscles. The inferior border gives attachment, in front, to the Sterno-hyoid; behind, to the Omo-hyoid and to part of the Thyro-hyoid at its junction with the great cornu. It also gives attachment to the Levator glandulae thyroidae when this muscle is present. The lateral surfaces are small, oval, convex facets, covered with cartilage for articulation with the greater cornua.

The Greater Cornua (thyro-hyal) project backward from the lateral surfaces of the body; they are flattened from above downward, diminish in size from before backward, and terminate posteriorly in a tubercle for the attachment of the lateral thyro-hyoid ligament. The outer surface gives attachment to the Hyo-glossus, their upper border to the Middle constrictor of the pharynx, their lower border to part of the Thyro-hyoid muscle. In youth the great cornua are connected to the body by cartilaginous surfaces and held together by ligaments; in middle life they usually become joined.

The Lesser Cornua (cerato-hyals) are two small, conical-shaped eminences attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylo-hyoid ligaments. The smaller cornua are connected to the body of the bone by a distinct diarthrodial joint, which usually persists throughout life, but occasionally becomes ankylosed.

Development.—By five centres: one for the body, and one for each cornu. Ossification commences in the body about the eighth month, and in the greater cornua toward the end of foetal life. Ossification of the lesser cornua commences some months after birth.

Attachment of Muscles.—Sterno-hyoid, Thyro-hyoid, Omo-hyoid, aponeurosis

These ligaments in many animals are distinct bones, and in man are occasionally ossified to a certain extent.
of the Digastric, Stylo-hyoid, Mylo-hyoid, Genio-hyoid, Genio-hyo-glossus, Chondro-glossus, Hyo-glossus, Middle constrictor of the pharynx, and occasionally a few fibres of the Lingualis. It also gives attachment to the thyro-hyoidian membrane and the stylo-hyoid, thyro-hyoid, and hyo-epiglottic ligaments.

Surface Form.—The hyoid bone can be felt in the receding angle below the chin, and the finger can be carried along the whole length of the bone to the greater cornu, which is situated just below the angle of the jaw. This process of bone is best perceived by making pressure on one cornu, and so pushing the bone over to the opposite side, when the cornu of this side will be distinctly felt immediately beneath the skin. This process of bone is an important landmark in ligature of the lingual artery.

Surgical Anatomy.—The hyoid bone is occasionally fractured, generally from direct violence, as in the act of garroting or throttling. The great cornu is the part of the bone most frequently broken, but sometimes the fracture takes place through the body of the bone. In consequence of the muscles of the tongue having important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

THE THORAX.

The Thorax, or Chest, is an osseo-cartilaginous cage containing and protecting the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backward, and longer behind than in front. It is somewhat cordiform on transverse section.

Boundaries.—The posterior surface is formed by the twelve dorsal vertebrae and the posterior part of the ribs. It is convex from above downward, and presents on each side of the middle line a deep groove in consequence of the direction backward and outward which the ribs take from their vertebral extremities to their angles. The anterior surface is flattened or slightly convex, and inclined forward from above downward. It is formed by the sternum and costal cartilages. The lateral surfaces are convex; they are formed by the ribs, separated from each other by spaces, the intercostal spaces. These are eleven in number, and are occupied by the intercostal muscles.

The upper opening of the thorax is reniform in shape, being broader from side to side than from before backward. It is formed by the first dorsal vertebra behind, the upper margin of the sternum in front, and the first rib on each side. It slopes downward and forward, so that the anterior part of the ring is on a lower level than the posterior. The antero-posterior diameter is about two inches. The lower opening is formed by the twelfth dorsal vertebra behind, by the twelfth rib at the sides, and in front by the cartilages of the eleventh, tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the subcostal angle, from the centre of which the ensiform cartilage projects. It is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm closes in the opening forming the floor of the thorax.

In the female the thorax differs as follows from the male: 1. Its general capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third dorsal vertebra, whereas in the male it is on a level with the lower part of the body of the second dorsal vertebra. 4. The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax than in the male.

The Sternum.

The Sternum (στήνον, the chest) (Figs. 179, 180) is a flat, narrow bone, situated in the median line of the front of the chest, and consisting, in the adult, of three portions. It has been likened to an ancient sword; the upper piece, representing the handle, is termed the manubrium; the middle and largest piece, which represents the chief part of the blade, is termed the gladiolus; and the inferior piece, which is likened to the point of the sword, is termed the ensiform or xiphoid appendix. In its natural position its inclination is oblique from above downward and forward. It is flattened in front, concave behind, broad above becoming
narrowed at the point where the first and second pieces are connected, after which it again widens a little, and is pointed at its extremity. Its average length in the adult is six inches, being rather longer in the male than in the female.

The First Piece of the sternum, or Manubrium (pre-sternum), is of a somewhat triangular form, broad and thick above, narrow below at its junction with the middle piece. Its anterior surface, convex from side to side, concave from above downward, is smooth, and affords attachment on each side to the Pectoralis major and sternal origin of the Sterno-cleido-mastoid muscle. In well-marked bones the ridges limiting the attachment of these muscles are very distinct. Its posterior surface, concave and smooth, affords attachment on each side to the Sterno-hyoid and Sterno-thyroid muscles. The superior border, the thickest, presents at its centre the pre-sternal notch; and on each side an oval articular surface, directed upward, backward, and outward, for articulation with the sternal end of the clavicle. The inferior border presents an oval, rough surface, covered in the recent state with a thin layer of cartilage, for articulation with the second portion of the bone. The lateral borders are marked above by a depression for the first costal cartilage, and below by a small facet, which with a similar facet on the upper angle of the middle portion of the bone, forms a notch for the reception of the costal cartilage of the second rib. These articular surfaces are separated by a narrow, curved edge, which slopes from above downward and inward.

The Second Piece of the sternum, or Gladiolus (meso-sternum), considerably longer, narrower, and thinner than the first piece, is broader below than above. Its anterior surface is nearly flat, directed upward and forward, and marked by three transverse lines which cross the bone opposite the third, fourth, and fifth articular depressions. These lines are produced by the union of the four separate pieces of which this part of the bone consists at an early period of life. At the junction of the third and fourth pieces is occasionally seen an orifice, the sternal foramen; it varies in size and form in different individuals, and pierces the bone from before backward. This surface affords attachment on each side to the sternal origin of the Pectoralis major. The posterior surface, slightly concave, is also marked by three transverse lines, but they are less distinct than those in front; this surface affords attachment below, on each side, to the Triangularis sterni muscle, and occasionally presents the posterior opening of the sternal foramen. The superior border presents an oval surface for articulation with the manubrium. The inferior border is narrow, and articulates with the ensiform appendix. Each lateral border presents, at each superior angle, a small facet, which, with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; the four succeeding angular depressions receive the cartilages of the third, fourth, fifth, and sixth ribs; whilst each inferior angle presents a small facet, which, with a corresponding one on the ensiform appendix, forms a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length from above downward, and correspond to the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the line of junction of two of its primitive component segments. This is well seen in many of the lower animals, where the separate parts of the bone remain ununited longer than in man. In this respect a striking analogy exists between the mode of connection of the ribs with the vertebral column and the connection of their cartilages with the sternal column.

The Third Piece of the sternum, the Ensiform or Xiphoid Appendix (meta-
sternum), is the smallest of the three; it is thin and elongated in form, cartilaginous in structure in youth, but more or less ossified at its upper part in the adult. Its anterior surface affords attachment to the chondro-xiphoid ligament; its posterior surface, to some of the fibres of the Diaphragm and Triangularis sterni muscles; its lateral borders, to the aponeurosis of the abdominal muscles. Above it articulates with the lower end of the gladiolus, and at each superior angle presents a facet for the lower half of the cartilage of the seventh rib; below, by
STERNO-CLIDOMASTOID.
SUBCLAVIUS.

FIG. 180. Posterior surface of sternum.
The sternum.

231

its pointed extremity it gives attachment to the linea alba. This portion of the sternum is very various in appearance, being sometimes pointed, broad, and thin, sometimes bifid or perforated by a round hole, occasionally curved or deflected considerably to one or the other side.

Structure.—The bone is composed of delicate cancellous structure, covered by a thin layer of compact tissue, which is thickest in the manubrium between the articular facets for the clavicles.

Development.—The sternum, including the ensiform appendix, is developed by six centres: one for the first piece or manubrium, four for the second piece or gladiolus, and one for the ensiform appendix. Up to the middle of feetal life the sternum is entirely cartilaginous, and when ossification takes place the ossific granules are deposited in the middle of the intervals between the articular depressions for the costal cartilages, in the following order (Fig. 181): In the first piece, between the fifth and sixth months; in the second and third, between the sixth and seventh months; in the fourth piece, at the ninth month; in the fifth, within the first year or between the first and second years after birth; and in the ensiform appendix, between the second and the seventeenth or eighteenth years, by a single centre which makes its appearance at the upper part and proceeds gradually downward. To these may be added the occasional existence, as described by Breschet, of two small episternal centres, which make their appearance one on each side of the interclavicular notch. They are probably vestiges of the episternal bone of the monotremata and lizards. It occasionally happens that some of the segments are formed from more than one centre, the number and position of which vary (Fig. 183). Thus, the first piece may have two, three, or even six centres. When
two are present, they are generally situated one above the other, the upper one being the larger;\(^1\) the second piece has seldom more than one; the third, fourth, and fifth pieces are often formed from two centres placed laterally, the irregular union of which will serve to explain the occasional occurrence of the sternal foramen (Fig. 184), or of the vertical fissure which occasionally intersects this part of the bone, and which is further explained by the manner in which the cartilaginous matrix, in which ossification takes place, is formed (see page 115). Union of the various centres of the gladiolus commences about puberty, from below, and proceeds upward, so that by the age of twenty-five they are all united, and this portion of bone consists of one piece (Fig. 182). The ensiform cartilage becomes joined to the gladiolus about forty. The manubrium is occasionally, but not invariably, joined to the gladiolus in advanced life by bone. When this union takes place, however, it is generally only superficial, a portion of the centre of the sutural cartilage remaining unossified.

**Articulations.**—With the clavicles and seven costal cartilages on each side.

**Attachment of Muscles.**—To nine pairs and one single muscle: the Pectoralis major, Sternocondido-mastoid, Sterno-hyoid, Sterno-thyroid, Triangularis sterni, aponeuroses of the Obliquis externus, Obliquis internus, Transversalis, Rectus muscles, and Diaphragm.

**The ribs.**

The Ribs are elastic arches of bone, which form the chief part of the thoracic walls. They are twelve in number on each side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the spine and in front with the sternum, through the intervention of the costal cartilages; they are called true ribs. The remaining five are false ribs; of these, the first three have their cartilages attached to the cartilage of the rib above: the last two are free at their anterior extremities; they are termed floating ribs. The ribs vary in their direction, the upper ones being less oblique than those lower down and occupying the middle of the series. The extent of obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs are situated one below the other in such a manner that spaces are left between them, which are called intercostal spaces. The length of these spaces corresponds to the length of the ribs; their breadth is more considerable in front than behind, and between the upper than

\(^1\) Sir George Humphry states that this is "probably the more complete condition."
between the lower ribs. The ribs increase in length from the first to the seventh, when they again diminish to the twelfth. In breadth they decrease from above downward; in the upper ten the greatest breadth is at the sternal extremity.

Common Characters of the Ribs (Fig. 185).—A rib from the middle of the series should be taken in order to study the common characters of the ribs.

Each rib presents two extremities, a posterior or vertebral, an anterior or sternal, and an intervening portion—the body or shaft.

The posterior or vertebral extremity presents for examination a head, neck, and tuberosity. The head (Fig. 186) is marked by a kidney-shaped articular surface, divided by a horizontal ridge into two facets for articulation with the costal cavity formed by the junction of the bodies of two contiguous dorsal vertebrae; the upper facet is small, the inferior one of larger size; the ridge separating them serves for the attachment of the interarticular ligament. The neck is that flattened portion of the rib which extends outward from the head; it is about an inch long, and is placed in front of the transverse process of the lower of the two vertebrae with which the head articulates. Its anterior surface is flat and smooth. Its posterior rough for the attachment of the middle costo-transverse ligament, and perforated by numerous foramina, the direction of which is less constant than those found on the inner surface of the shaft. Of its two borders the superior presents a rough crest for the attachment of the anterior costo-transverse ligament; its inferior border is rounded. On the posterior surface of the neck, just where it

joins the shaft, and nearer the lower than the upper border, is an eminence—the tuberosity, or tubercle; it consists of an articular and a non-articular portion. The articular portion, the more internal and inferior of the two, presents a small, oval surface for articulation with the extremity of the transverse process of the lower of the two vertebrae to which the head is connected. The non-articular portion is a rough elevation, which affords attachment to the posterior costo-transverse ligament. The tubercle is much more prominent in the upper than in the lower ribs.

The shaft is thin and flat, so as to present two surfaces, an external and an internal, and two borders, a superior and an inferior. The external surface is convex, smooth and marked at its back part, a little in front of the tuberosity, by a prominent line, directed obliquely from above downward and outward; this gives attachment to a tendon of the Ilio-costalis muscle or of one of its accessory portions, and is called the angle. At this point the rib is bent in two directions. If the rib is laid upon its lower border, it will be seen that the portion of the shaft in front of the angle rests upon this border, while the portion of the shaft behind the angle is bent inward and at the same time tilted upward. The interval between the angle and the tuberosity increases gradually from the second to the tenth rib. The portion of bone between these two parts is rounded, rough, and irregular, and serves for the attachment of the Longissimus dorsi muscle. The portion of bone between the tubercle and sternal extremity is also slightly twisted upon its own axis, the external surface looking downward behind the angle, a little upward in front of it. This surface presents, toward its sternal extremity, an oblique line, the anterior angle. The internal surface is concave, smooth, directed a little upward behind the angle, a little downward in front of it. This surface is marked by a ridge which commences at the lower extremity of the head; it is
strongly marked as far as the inner side of the angle, and gradually becomes lost at the junction of the anterior with the middle third of the bone. The interval between it and the inferior border is deeply grooved, to lodge the intercostal vessels and nerve. At the back part of the bone this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it corresponds to the internal surface. The superior edge of the groove is rounded; it serves for the attachment of the Internal intercostal muscle. The inferior edge corresponds to the lower margin of the rib and gives attachment to the External intercostal. Within the groove are seen the orifices of numerous small foramina which traverse the wall of the shaft obliquely from before backward. The superior border, thick and rounded, is marked by an external and an internal lip, more distinct behind than in front; they serve for the attachment of the External and Internal intercostal muscles. The inferior border, thin and sharp, has attached to it the External intercostal muscle. The anterior or sternal extremity is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

Peculiar Ribs.

The ribs which require especial consideration are five in number—viz. the first, second, tenth, eleventh and twelfth.

The first rib (Fig. 187) is one of the shortest and the most curved of all the ribs; it is broad and flat, its surfaces looking upward and downward, and its borders inward and outward. The head is of small size, rounded, and presents only a single articular facet for articulation with the body of the first dorsal vertebra. The neck is narrow and rounded. The tuberosity, thick and prominent, rests on the outer border. There is no angle, but in this situation the rib is slightly bent, with the convexity of the bend upward, so that the head of the bone is directed downward. The upper surface of the shaft is marked by two shallow depressions, separated from one another by a small rough surface for the attachment of the Scalenus anticus muscle—the groove in front of it transmitting the subclavian vein, that behind it the subclavian artery. Between the groove for the subclavian artery and the tuberosity is a rough surface, for the attachment of the Scalenus medius muscle. The under surface is smooth, and destitute of the groove observed on the other ribs. The outer border is convex, thick, and rounded, and at its posterior part gives attachment to the first serration of the Serratus magnus; the inner is concave, thin, and sharp, and marked about its centre by the commencement of the rough surface for the Scalenus anticus. The anterior extremity is larger and thicker than any of the other ribs.

The second rib (Fig. 188) is much longer than the first, but bears a very considerable resemblance to it in the direction of its curvature. The non-articular portion of the tuberosity is occasionally only slightly marked. The angle is slight and situated close to the tuberosity, and the shaft is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a similar though slighter bend, with its convexity upward, to that found in the first rib. The shaft is not horizontal, like that of the first rib, its outer surface, which is convex, looking upward and a little outward. It presents, near the middle, a rough eminence for the attachment of the second and third digitations of the Serratus magnus; behind and above which is attached the Scalenus posticus. The inner surface, smooth and concave, is directed downward and a little inward; it presents a short groove toward its posterior part.

The tenth rib (Fig. 189) has only a single articular facet on its head.

The eleventh and twelfth ribs (Figs. 190 and 191) have each a single articular facet on the head, which is of rather large size; they have no neck or tuberosity, and are pointed at the extremity. The eleventh has a slight angle and a shallow groove on the lower border. The twelfth has neither, and is much shorter than the eleventh, and the head has a slight inclination downward.

Structure.—The ribs consist of cancellous tissue enclosed in a thin, compact layer.
PECULIAR RIBS.

Development.—Each rib, with the exception of the last two, is developed by three centres: one for the shaft, one for the head, and one for the tubercle. The last two have only two centres, that for the tubercle being wanting. Ossification commences in the shaft of the ribs at a very early period, before its appearance in the vertebrae. The epiphysis of the head, which is of slightly angular shape, and that for the tubercle, of a lenticular form, make their appearance between the sixteenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year.

Attachment of Muscles.—The Internal and External intercostals, Scalenus anticus, Scalenus medius, Scalenus posticus, Pectoralis minor, Serratus magnus, Obliquus externus, Obliquus internus, Transversalis, Quadratus lumborum, Diaphragm, Latissimus dorsi, Serratus posticus superior, Serratus posticus inferior, Ilio-costalis, Musculus accessorius ad ilio-costalem, Longissimus dorsi, Cervicalis ascendens, Levatores costarum, and Infracostales.
The Costal Cartilages.

The Costal Cartilages (Fig. 179, p. 230) are white, elastic structures, which serve to prolong the ribs forward to the front of the chest, and contribute very materially to the elasticity of its walls. The first seven are connected with the sternum, the next three with the lower border of the cartilage of the preceding rib. The cartilages of the last two ribs, which have pointed extremities, float freely in the walls of the abdomen. Like the ribs, the costal cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually diminish to the last. They diminish in breadth, as well as the intervals between them, from the first to the last. They are broad at their attachment to the ribs, and taper toward their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh and eighth, which are enlarged where their margins are in contact. In direction they also vary: the first descends a little, the second is horizontal, the third ascends slightly, whilst all the rest follow the course of the ribs for a short extent, and then ascend to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities. The anterior surface is convex, and looks forward and upward: that of the first gives attachment to the costo-clavicular ligament and the Subclavius muscle; that of the second, third, fourth, fifth, and sixth, at their sternal ends, to the Pectoralis major. The others are covered by, and give partial attachment to, some of the great flat muscles of the abdomen. The posterior surface is concave, and directed backward and downward, the first giving attachment to the Sternal-thyroid, and the six or seven inferior ones affording attachment to the Transversalis muscle and the Diaphragm. Of the two borders, the superior is concave, the inferior convex: they afford attachment to the Intercostal muscles, the upper border of the sixth giving attachment to the Pectoralis major muscle. The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages present small, smooth, oblong-shaped facets at the points where they articulate. Of the two extremities, the outer one is continuous with the osseous tissue of the rib to which it belongs. The inner extremity of the first is continuous with the sternum; the six succeeding ones have rounded extremities, which are received into shallow concavities on the lateral margins of the sternum. The inner extremities of the eighth, ninth, and tenth costal cartilages are pointed, and are connected with the cartilage above. Those of the eleventh and twelfth are free and pointed.

The costal cartilages are most elastic in youth, those of the false ribs being more so than the true. In old age they become of a deep yellow color, and are prone to calcify.

Attachment of Muscles.—To nine: the Subclavius, Sternal-thyroid, Pectoralis major, Internal oblique, Transversalis, Rectus, Diaphragm, Triangularis sterni, and Internal intercostals.

Surface Form.—The bones of the chest are to a very considerable extent covered by muscles, so that in the strongly-developed muscular subject they are for the most part concealed. In the emaciated subject, on the other hand, the ribs, especially in the lower and lateral region, stand out as prominent ridges with the sunken, intercostal spaces between them.

In the middle line, in front, the superficial surface of the sternum is to be felt throughout its entire length, at the bottom of a deep median furrow situated between the two great pectoral muscles and called the sternal furrow. These muscles overlap the anterior surface somewhat, so that the whole of the sternum in its entire width is not subcutaneous; and this overlapping is greater opposite the centre of the bone than above and below, so that the furrow is wider at its upper and lower parts, but narrower in the middle. The centre of the upper border of the sternum is visible, constituting the pre-sternal notch, but the lateral parts of this border are obscured by the tendinous origins of the Sternal-mastoid muscles, which present themselves as oblique tendinous cords, which narrow and deepen the notch. Lower down on the subcutaneous surface a well-defined transverse ridge is always to be felt. This denotes the line of junction of the manubrium and body of the bone, and is a useful guide to the second costal cartilage, and thus to the identity of any given rib. The second rib being found through its costal cartilage,

1 The first and seventh also, occasionally, give origin to the same muscle.
it is easy to count downward and find any other. Below this point the furrow spreads out, and, exposing more of the surface of the body of the sternum, terminates below in a sudden depression, the infrasternal depression or pit of the stomach (scrobulcus cordis), which corresponds to the esinous cartilage. This depression lies between the cartilages of the seventh rib, and in it the esinous cartilage may be felt. The sternum in its vertical diameter presents a general arching forward, the most prominent point of which is at the joint between the manubrium and gladiolus.

On each side of the sternum the costal cartilages and ribs on the front of the chest are partially obscured by the great pectoral muscle; through which, however, they are to be felt as ridges, with depressed intervals between them, corresponding to the intercostal spaces. Of these spaces, the one between the second and third ribs is the widest, the next two somewhat narrower, and the remainder, with the exception of the last two, comparatively narrow.

The lower border of the Pectoralis major muscle corresponds to the fifth rib, and below this, on the front of the chest, the broad, flat outline of the ribs, as they begin to ascend, and the more rounded outline of the costal cartilages, are often visible. The lower boundary of the front of the thorax, the abdominal-thoracic arch, which is most plainly seen by arching the body backward, is formed by the esinous cartilage and the cartilages of the seventh, eighth, ninth, and tenth ribs, and the extremities of the eleventh and twelfth ribs or their cartilages.

On each side of the chest, from the axilla downward, the flattened external surfaces of the ribs may be defined in the form of oblique ridges, separated by depressions corresponding to the intercostal spaces. They are, however, covered by muscles, which obscure their outline to a certain extent in the strongly developed. Nevertheless, the ribs, with the exception of the first, can generally be followed over the front of the chest, and being almost completely covered by the carinate and scapular cartilage, can only be distinguished in a small portion of their extent. At the back the angles of the ribs form a slightly-marked oblique line on each side and a short distance from the vertebral spines. This line diverges somewhat as it descends, and external to it is a broad, convex surface caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

Surgical Anatomy.—Malformations of the sternum present nothing of surgical importance beyond the fact that abscesses of the mediastinum may sometimes escape through the sternal foramen. Fractures of the sternum are by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages, which support it like so many springs. It is frequently associated with fracture of the spine, and may be caused by forcibly bending the body either backward or forward until the chin becomes impacted against the top of the sternum. It may also be fractured by direct violence, or by muscular action. The fracture usually occurs in the upper half of the body. Dislocation of the gladiolus from the manubrium also takes place, and is sometimes described as a fracture.

The bone, being subcutaneous, is frequently the seat of gummatous tumors, and not uncommonly is affected with caries. Occasionally the bone, and especially its esinous appendix, becomes altered in shape and driven inward by the pressure, in workmen, of tools against their chest.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle of the series are the ones most liable to fracture. The first, and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth, on account of their loose and flexible condition, enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the chest-wall, and the bone then gives way at its weakest part—i.e., just in front of the angle. But the ribs may also be broken by direct violence, when the bone gives way and is driven inward at the point struck, or by muscular action. It seems probable, however, that in these latter cases the bone has undergone some atrophic changes. Fracture of the ribs is frequently complicated with some injury to the visera contained within the thorax or upper part of the abdominal cavity, and this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages may also take place, though it is a comparatively rare injury. The thorax is frequently found to be altered in shape in certain diseases.

Fracture of the chest is caused chiefly by atmospheric pressure. The balance between the air on the inside of the chest and the outside of the chest is not equal, the preponderance being in favor of the air outside; and this, acting on the softened ribs, causes them to be forced in at the junction of the cartilages with the bones, which is the weakest part. In consequence of this the sternum projects forward, with a deep depression on either side caused by the sinking in of the softened ribs. The depression is less on the left side, on account of the ribs being supported by the heart. The condition is known as "pigeon-breast." The lower ribs, however, are not involved in this deformity, as they are prevented from falling in by the presence of the stomach, liver, and spleen. And when the liver and spleen are enlarged, as they sometimes are in rickets, the lower ribs may be pushed outward; this causes a transverse constriction just above the costal arch. The anterior extremities of the ribs are usually enlarged in rickets, giving rise to what has been termed the "rickety rosary." The phthihusl chest is often long and narrow, flattened from before backward, and with great obliquity of the ribs and projection of the scapula. In pulmonary emphysema the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the
"barrel-shaped chest." In severe cases of lateral curvature of the spine the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebrae which takes place in this disease the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same time flattened in front, so that the two ends of the same rib are almost parallel. Coincident with this, the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind and bulging and convex in front. In addition to this the ribs become occasionally welded together by bony material. The ribs are frequently the seat of necrosis leading to abscesses and sinuses, which may burrow to a considerable extent over the wall of the chest. The only special anatomical point in connection with these is that care must be taken in dealing with them that the intercostal space is not punctured and the pleural cavity opened or the intercostal vessels wounded.

In cases of empyema the chest requires opening to evacuate the pus. There is considerable difference of opinion as to the best position to do this. Probably the best place in most cases will be found to be between the fifth and sixth ribs, in or a little in front of the mid-axillary line. This is the last part of the cavity to be closed by the expansion of the lung; it is not thickly covered by soft parts; the space between the two ribs is sufficiently great to allow of the introduction of a fair-sized drainage-tube, and the opening is in a dependent position, when the patient is confined to bed, as he usually inclines toward the affected side, so as to allow the sound lung the freest possible play, and so permits of efficient drainage.

OF THE EXTREMITIES.

The extremities, or limbs, are those long, jointed appendages of the body which are connected to the trunk by one end and free in the rest of their extent. They are four in number: an upper or thoracic pair, connected with the thorax through the intervention of the shoulder, and subervient mainly to prehension; and a lower pair, connected with the pelvis, intended for support and locomotion. Both pairs of limbs are constructed after one common type, so that they present numerous analogies, while at the same time certain differences are observed in each, dependent on the peculiar offices they have to perform.

The bones by which the upper and lower limbs are attached to the trunk are named respectively the shoulder and pelvic girdles, and they are constructed on the same general type, though presenting certain modifications relating to the different uses to which the upper and lower limbs are respectively applied. The shoulder girdle is formed by the scapula and clavicle, and is imperfect in front and behind. In front, however, the girdle is completed by the upper end of the sternum, with which the inner extremities of the clavicle articulate. Behind, the girdle is widely imperfect and the scapula is connected to the trunk by muscles only. The pelvic girdle is formed by the innominate bones, and is completed in front through the symphysis pubis, at which the two innominate bones articulate with each other. It is imperfect behind, but the intervening gap is filled in by the upper part of the sacrum. The pelvic girdle, therefore, presents, with the sacrum, a complete ring, comparatively fixed, and presenting an arched form which confers upon it a solidity manifestly intended for the support of the trunk, and in marked contrast to the lightness and mobility of the shoulder girdle.

With regard to the morphology of these girdles, the blade of the scapula is generally believed to correspond to the ilium; but with regard to the clavicles there is some difference of opinion: formerly it was believed that they corresponded to the osa pubis, meeting at the symphysis, but it is now generally taught that the clavicle has no homologue in the pelvic girdle, and that the os pubis and ischium are represented by the small coracoid process in man and most mammals.

THE UPPER EXTREMITY.

The bones of the upper extremity consist of those of the shoulder girdle, of the arm, the forearm, and the hand. The shoulder girdle consists of two bones, the clavicle and the scapula.

THE SHOULDER.

The Clavicle.

The Clavicle (clavis, a key), or collar-bone, forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter f, and
placed nearly horizontally at the upper and anterior part of the thorax, immediately above the first rib. It articulates by its inner extremity with the upper border of the sternum, and by its outer extremity with the acromion process of the scapula, serving to sustain the upper extremity in the various positions which it assumes, whilst at the same time it allows of great latitude of motion in the arm. It presents a double curvature when looked at in front, the convexity being forward at the sternal end and the concavity at the scapular end. Its outer third is flattened from above downward, and extends, in the natural position of the bone, from a point opposite the coracoid process to the acromion. Its inner two-thirds are of a cylindrical form, and extend from the sternum to a point opposite the coracoid process of the scapula.

**External or Flattened Portion.**—The outer third is flattened from above downward, so as to present two surfaces, an upper and a lower; and two borders, an anterior and a posterior. The upper surface is flattened, rough, marked by impressions for the attachment of the Deltoid in front and the Trapezius behind; between these two impressions, externally, a small portion of the bone is subcutaneous. The under surface is flattened. At its posterior border, a little external to the point where the prismatic joins with the flattened portion, is a rough eminence, the conoid tubercle; this, in the natural position of the bone, surrounds the coracoid process of the scapula and gives attachment to the conoid ligament. From this tubercle an oblique line, occasionally a depression, passes forward and outward to near the outer end of the anterior border; it is called the oblique line, and affords attachment to the trapezoid ligament. The anterior border is concave, thin, and rough, and gives attachment to the Deltoid; it occasionally presents, at its inner end, at the commencement of the deltoid impression, a tubercle, the deltoid tubercle, which is sometimes to be felt in the living subject. The posterior border is convex, rough, broader than the anterior, and gives attachment to the Trapezius.

**Internal or Cylindrical Portion.**—The cylindrical portion forms the inner two-thirds of the bone. It is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces. The anterior border is continuous with the anterior margin of the flat portion. At its commencement it is smooth, and corresponds to the interval between the attachment of the Pectoralis major and Deltoid muscles; at the inner half of the clavicle it forms the lower boundary of an elliptical space for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone. The superior border is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. At its commencement it is smooth and rounded, becomes rough toward the inner third for the attachment of the Sterno-mastoid muscle, and terminates at the upper angle of the sternal extremity. The posterior or subclavian border separates the posterior from the inferior surface, and extends from the conoid tubercle to the rhomboid impression. It forms the posterior boundary of the groove for the Subclavius muscle, and gives attachment to a layer of cervical fascia covering the Omo-hyoid muscle. The anterior surface is included between the superior and anterior borders. It is directed forward and a little upward at the sternal end, outward and still more upward at the acromial extremity, where it becomes continuous with the upper surface of the flat portion. Externally, it is smooth, convex, nearly subcutaneous, being covered only by the Platysma; but, corresponding to the inner half of the bone, it is divided by a more or less prominent line into two parts: a lower portion, elliptical in form, rough, and slightly-convex, for the attachment of the Pectoralis major; and an upper part, which is rough, for the attachment of the Sterno-cleido-mastoid. Between

---

1 The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore limbs are used only for progression, but is present for the most part in those animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating either with the scapula or sternum.
the two muscular impressions is a small subcutaneous interval. The posterior or cervical surface is smooth, flat, and looks backward toward the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; internally, by the margin of the sternal extremity; externally, it is continuous with the posterior border of the flat portion. It is concave from within outward, and is in relation, by its lower part, with the suprascapular vessels. This surface, at about the junction of the inner and outer curves, is also in close relation with the brachial plexus and subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sterno-hyoid muscle; and presents, at or near the middle, a foramen, directed obliquely outward, which transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior, the other on the inferior surface. The inferior or subclavian surface is bounded, in front, by the anterior border; behind, by the subclavian border. It is narrow internally, but gradually increases in width externally, and is continuous with the under surface of the flat portion. Commencing at the sternal extremity may be seen a small facet for articulation with the cartilage of the first rib. This is continuous with the articular surface at the sternal end of the bone. External to this is a broad, rough impression, the rhomboid, rather more than an inch in length, for the attachment of the costo-clavicular (rhomboid) ligament. The remaining part of this surface is occupied by a longitudinal groove, the subclavian groove, broad and smooth externally, narrow and more uneven internally; it gives attachment to the Subclavius muscle, and by its anterior margin to the costo-coracoid membrane. Not unfrequently this groove is subdivided into two parts by a longitudinal line, which gives attachment to the intermuscular septum of the Subclavius muscle.

The internal or sternal extremity of the clavicle is triangular in form, directed inward and a little downward and forward; and presents an articular facet, concave from before backward, convex from above downward, which articulates with the sternum through the intervention of an interarticular fibro-cartilage; the circumference of the articular surface is rough, for the attachment of numerous
the ligaments. The posterior border of this surface is prolonged backward, so as to increase the size of the articular facet; the upper border gives attachment to the interarticular fibro-cartilage, and the lower border is continuous with the costal facet on the inner end of the inferior or subclavian surface, which articulates with the cartilage of the first rib.

The outer or acromial extremity, directed outward and forward, presents a small, flattened, oval facet, which looks obliquely downward, for articulation with the acromion process of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromio-clavicular ligaments.

Peculiarities of the Bone in the Sexes and in Individuals.—In the female the clavicle is generally shorter, thinner, less curved, and smoother than in the male.

In those persons who perform considerable manual labor, which brings into constant action the muscles connected with this bone, it becomes thicker and more curved, its ridges for muscular attachment become prominently marked, and its sternal end of a prismatic form. The right clavicle is generally longer, thicker, and rougher than the left.

Structure.—The shaft, as well as the extremities, consists of cancellous tissue, invested in a compact layer much thicker in the middle than at either end. The clavicle is highly elastic, by reason of its curves. From the experiments of Mr. Ward it has been shown that it possesses sufficient longitudinal elastic force to project its own weight nearly two feet on a level surface when a smart blow is struck on it; and sufficient transverse elastic force, opposite the centre of its anterior convexity, to throw its own weight about a foot. This extent of elastic power must serve to moderate very considerably the effect of concussions received upon the point of the shoulder.

Development.—By two centres: one for the shaft and one for the sternal extremity. The centre for the shaft appears very early, before any other bone—according to Béclard, as early as the thirtieth day. The centre for the sternal end makes its appearance about the eighteenth or twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Articulations.—With the sternum, scapula, and cartilage of the first rib.

Attachment of Muscles.—To six: the Serrato-cleido-mastoid, Trapezius, Pectoralis major, Deltoid, Subclavius, and Sterno-hyoid.

Surface Form.—The clavicle can be felt throughout its entire length, even in persons who are very fat. Commencing at the inner end, the enlarged sternal extremity, where the bone projects above the upper margin of the sternum, can be felt, forming with the sternum and the rounded tendon of the Serrato-mastoid a V-shaped notch, the pre-sternal notch. Passing outward, the shaft of the bone can be felt immediately under the skin, with its convexity forward in the inner two-thirds, the surface partially obscured above and below by the attachments of the Serrato-mastoid and Pectoralis major muscles. In the outer third it forms a gentle curve backward, and terminates at the outer end in a somewhat enlarged extremity which articulates with the acromial process of the scapula. The direction of the clavicle is almost, if not quite, horizontal when the arm is lying quietly by the side, though in well-developed subjects it may incline a little upward at its outer end. Its direction is, however, very changeable with the varying movements of the shoulder-joint.

Surgical Anatomy.—The clavicle is the most frequently broken of any single bone in the body. This is due to the fact that it is much exposed to violence, and is the only bony connection between the upper limb and the trunk. The bone, moreover, is slender, and is very superficial. The bone may be broken by direct or indirect violence or by muscular action. The most common cause is, however, from indirect violence, and the bone then gives way at the junction of the outer with the inner two-thirds of the bone; that is to say at the junction of the two curves, for this is the weakest part of the bone. The fracture is generally oblique, and the displacement of the fragments is inward, away from the surface of the body; hence compound fracture of the clavicle is of rare occurrence. Beneath the bone the main vessels of the upper limb and the great nerve-cords of the brachial plexus lie on the first rib, and are liable to be wounded in fracture, especially in fracture from direct violence, when the force of the blow drives the broken ends inward. Fortunately, the Subclavius muscle is interposed between these structures and the clavicle, and this often protects them from injury.

The clavicle is not uncommonly the seat of sarcomatous tumors, rendering the operation of excision of the entire bone necessary. This is an operation of considerable difficulty and danger. It is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it inward. The removal of the outer part is comparatively easy, but resection of
the inner part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its under surface.

The Scapula.

The Scapula (σκαπυλα, a spade) forms the back part of the shoulder girdle. It is a large, flat bone, triangular in shape, situated at the posterior aspect and side of the thorax, between the second and seventh, or sometimes the eighth, ribs, its posterior border or base being about an inch from, and nearly, but not quite parallel with the spinous processes of the vertebrae, so that it is rather closer to them above than below. It presents for examination two surfaces, three borders, and three angles.

The anterior surface, or venter (Fig. 194), presents a broad concavity, the subscapular fossa. It is marked, in the posterior two-thirds, by several oblique ridges, which pass from behind obliquely outward and upward; the anterior third is smooth. The oblique ridges give attachment to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Subscapularis muscle. The

Fig. 194.—Left scapular anterior surface, or venter.
anterior third of the fossa, which is smooth, is covered by, but does not afford attachment to, the fibres of this muscle. The venter is separated from the posterior border by a smooth, triangular margin at the superior and inferior angles, and in the interval between these by a narrow edge which is often deficient. This marginal surface affords attachment throughout its entire extent to the Serratus magnus muscle. The subscapular fossa presents a transverse depression at its upper part, where the bone appears to be bent on itself, forming a considerable angle, called the subscapular angle, thus giving greater strength to the body of the bone from its arched form, while the summit of the arch serves to support the spine and acromion process. It is in this situation that the fossa is deepest, so that the thickest part of the Subscapularis muscle lies in a line perpendicular to the plane of the glenoid cavity, and must consequently operate most effectively on the head of the humerus, which is contained in that cavity.

The posterior surface, or dorsum (Fig. 195), is arched from above downward, alternately concave and convex from side to side. It is subdivided unequally into
two parts by the spine: the portion above the spine is called the supraspinous fossa, and that below it the infraspinous fossa.

The supraspinous fossa, the smaller of the two, is concave, smooth, and broader at the vertebral than at the humeral extremity. It affords attachment by its inner two-thirds to the Supraspinatus muscle.

The infraspinous fossa is much larger than the preceding; toward its vertebral margin a shallow concavity is seen at its upper part; its centre presents a prominent convexity, whilst toward the axillary border is a deep groove which runs from the upper toward the lower part. The inner two-thirds of this surface affords attachment to the Infraspinatus muscle; the outer third is only covered by it, without giving origin to its fibres. This surface is separated from the axillary border by an elevated ridge, which runs from the lower part of the glenoid cavity downward and backward to the posterior border, about an inch above the inferior angle. The ridge serves for the attachment of a strong aponeurosis which separates the Infraspinatus from the two Teres muscles. The surface of bone between this line and the axillary border is narrow in the upper two-thirds of its extent, and traversed near its centre by a groove for the passage of the dorsalis scapulae vessels; it affords attachment to the Teres minor. Its lower third presents a broader, somewhat triangular surface, which gives origin to the Teres major, and over which the Latissimus dorsi glides; sometimes the latter muscle takes origin by a few fibres from this part. The broad and narrow portions of bone above alluded to are separated by an oblique line which runs from the axillary border, downward and backward, to meet the elevated ridge: to it is attached the aponeurosis separating the two Teres muscles from each other.

The Spine is a prominent plate of bone which crosses obliquely the inner four-fifths of the dorsum of the scapula at its upper part, and separates the supra- from the infraspinous fossa: it commences at the vertebral border by a smooth, triangular surface, over which the Trapezius glides, separated from the bone by a bursa, and, gradually becoming more elevated as it passes forward, terminates in the acromion process, which overhangs the shoulder-joint. The spine is triangular and flattened from above downward, its apex corresponding to the posterior border, its base (which is directed outward) to the neck of the scapula. It presents two surfaces and three borders. Its superior surface is concave, assists in forming the supraspinous fossa, and affords attachment to part of the Supraspinatus muscle. Its inferior surface forms part of the infraspinous fossa, gives origin to part of the Infraspinatus muscle, and presents near its centre the orifice of a nutrient canal. Of the three borders, the anterior is attached to the dorsum of the bone; the posterior, or crest of the spine, is broad, and presents two lips and an intervening rough interval. To the superior lip is attached the Trapezius to the extent shown in the figure. A rough tubercle is generally seen occupying that portion of the spine which receives the insertion of the middle and inferior fibres of this muscle. To the inferior lip, throughout its whole length, is attached the Deltoid. The interval between the lips is also partly covered by the fibres of these muscles. The external border, or base, the shortest of the three, is slightly concave, its edge thick and round, continuous above with the under surface of the acromion process, below with the neck of the scapula. The narrow portion of bone external to this border, and separating it from the glenoid cavity, is called the great scapular notch, and serves to connect the supraspinous fossa.

The Acromion Process, so called from forming the summit of the shoulder (ἀκρων, a summit; ἄμαξ, the shoulder), is a large and somewhat triangular process, flattened from behind forward, directed at first a little outward, and then curving forward and upward, so as to overhang the glenoid cavity. Its upper surface, directed upward, backward, and outward, is convex, rough, and gives attachment to some fibres of the Deltoid, and in the rest of its extent it is subcutaneous. Its under surface is smooth and concave. Its outer border is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoid muscle. Its inner margin, shorter than the outer, is concave, gives attachment to a portion
of the Trapezius muscle, and presents about its centre a small oval surface for articulation with the acromial end of the clavicle. Its apex, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coraco-acromial ligament.

Of the three borders or costae of the scapula, the superior is the shortest and thinnest; it is concave, terminating at its inner extremity at the superior angle, at its outer extremity at the coracoid process. At its outer part is a deep, semicircular notch, the suprascapular, formed partly by the base of the coracoid process. This notch is converted into a foramen by the transverse ligament, and serves for the passage of the suprascapular nerve. The adjacent margin of the superior border affords attachment to the Omo-hyoid muscle. The external, or axillary, border is the thickest of the three. It commences above at the lower margin of the glenoid cavity, and inclines obliquely downward and backward to the inferior angle. Immediately below the glenoid cavity is a rough impression (the infraglenoid tubercle), about an inch in length, which affords attachment to the long head of the Triceps muscle; to this succeeds a longitudinal groove, which extends as far as its lower third and affords origin to part of the Subscapularis muscle. The inferior third of this border, which is thin and sharp, serves for the attachment of a few fibres of the Teres major behind and of the Subscapularis in front. The internal, or vertebral, border, also named the base, is the longest of the three, and extends from the superior to the inferior angle of the bone. It is arched, intermediate in thickness between the superior and the external borders, and the portion of it above the spine is bent considerably outward, so as to form an obtuse angle with the lower part. The vertebral border presents an anterior lip, a posterior lip, and an intermediate space. The anterior lip affords attachment to the Serratus magnus; the posterior lip, to the Supraspinatus above the spine, the Infraspinatus below; the interval between the two lips, to the Levator anguli scapulae above the triangular surface at the commencement of the spine, the Rhomboideus minor to the edge of that surface; the Rhomboideus major being attached by means of a fibrous arch connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the posterior border.

Of the three angles, the superior, formed by the junction of the superior and internal borders, is thin, smooth, rounded, somewhat inclined outward, and gives attachment to a few fibres of the Levator anguli scapulae muscle. The inferior angle, thick and rough, is formed by the union of the vertebral and axillary borders, its outer surface affording attachment to the Teres major and occasionally a few fibres of the Latissimus dorsi. The anterior angle is the thickest part of the bone, and forms what is called the head of the scapula. The head presents a shallow, pyriform, articular surface, the glenoid cavity (\(\gamma\lambda\nu\epsilon\delta\)\(\nu\), a socket), whose longest diameter is from above downward, and its direction outward and forward. It is broader below than above; at its apex is a slight impression (supraglenoid tubercle) to which is attached the long tendon of the Biceps muscle. It is covered with cartilage in the recent state; and its margins, slightly raised, give attachment to a fibro-cartilaginous structure, the glenoid ligament, by which its cavity is deepened. The neck of the scapula is the slightly depressed surface which surrounds the head; it is more distinct on the posterior than on the anterior surface, and below than above. In the latter situation it has arising from it a thick prominence, the coracoid process.

The Coracoid Process, so called from its fancied resemblance to a crow’s beak (\(\zappa\rho\alpha\zeta\), a crow), is a thick, curved process of bone which arises by a broad base from the upper part of the neck of the scapula; it is directed at first upward and inward, then, becoming smaller, it changes its direction and passes forward and outward. The ascending portion, flattened from before backward, presents in front a smooth, concave surface over which passes the Subscapularis muscle. The horizontal portion is flattened from above downward, its upper surface is convex and irregular, and gives attachment to the Pectoralis minor; its under surface is
smooth; its inner border is rough, and gives attachment to the Pectoralis minor; its outer border is also rough for the coraco-acromial ligament, while the apex is embraced by the conjoined tendon of origin of the short head of the Biceps and of the Coraco-brachialis. At the inner side of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forward and outward on the upper surface of the horizontal portion, an elevated ridge for the attachment of the trapezoid ligament.

Structure.—In the head, processes, and all the thickened parts of the bone the scapula is composed of cancellous tissue, while in the rest of its extent it is composed of a thin layer of dense, compact tissue. The centre and upper part of the dorsum, but especially the former, are usually so thin as to be semitransparent; occasionally the bone is found wanting in this situation, and the adjacent muscles come into contact.

Development (Fig. 196).—By seven centres. The epiphyses (except one for the coracoid process) appear from fifteen to seventeen years, and unite between twenty-two and twenty-five years of age.

Ossification of the body of the scapula commences about the second month of fetal life by the formation of an irregular quadrilateral plate of bone immediately behind the glenoid cavity. This plate extends itself so as to form the chief part of the bone, the spine growing up from its posterior surface about the third month. At birth the chief part of the scapula is osseous, only the coracoid and acromion processes, the posterior border, and inferior angle being cartilaginous. About the first year after birth ossification takes place in the middle of the coracoid process, which usually becomes joined with the rest of the bone at the time when the other centres make their appearance. Between the fifteenth and seventeenth years ossification of the remaining centres takes place in quick succession, and
in the following order: firstly, near the base of the acromion and in the root of the coracoid process, the latter appearing in the form of a broad scale; secondly, in the inferior angle and contiguous part of the posterior border; thirdly, near the extremity of the acromion; fourthly, in the posterior border. The acromion process, besides being formed of two separate nuclei, has its base formed by an extension into it of the centre of ossification which belongs to the spine, the extent of which varies in different cases. The two separate nuclei unite, and then join with the extension carried in from the spine. These various epiphyses become joined to the bone between the ages of twenty-two and twenty-five years. Sometimes failure of union between the acromion process and spine occurs, the junction being effected by fibrous tissue or by an imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union it is probable that the detached segment was never united to the rest of the bone. Very often, in addition to these, a minute epiphysis appears at the margin of the glenoid cavity.

**Articulations.**—With the humerus and clavicle.

**Attachment of Muscles.**—To seventeen; to the anterior surface, the Subscapularis; posterior surface, Supraspinatus, Infraspinatus; spine, Trapezius, Deltoid; superior border, Omo-hyoid; vertebral border, Serratus magnus, Levator anguli scapulae, Rhomboideus minor and major; axillary border, Triceps, Teres minor, Teres major; glenoid cavity, long head of the Biceps; coracoid process, short head of the Biceps, Coraco-brachialis, Pectoralis minor; and to the inferior angle occasionally a few fibres of the Latissimus dorsi.

**Surface Form.**—The only parts of the scapula which are truly subcutaneous are the spine and acromion process, but, in addition to these, the coracoid process, the internal or vertebral border and inferior angle, and, to a less extent, the axillary border, may be defined. The acromion process and spine of the scapula are easily felt throughout their entire length, forming, with the clavicle, the arch of the shoulder. The acromion can be ascertained to be connected to the clavicle at the acromio-clavicular joint by running the finger along it, its position being often indicated by an irregularity or bony outgrowth from the clavicle close to the joint. The acromion can be felt forming the point of the shoulder, and from this can be traced backward to join the spine of the scapula. The place of junction is usually denoted by a prominence, which is sometimes called the angle. From here the spine can be felt as a prominent ridge of bone, marked on the surface as an oblique depression, which becomes less and less distinct, and terminates a slight external to the spinous processes of the vertebræ. Its termination is usually indicated by a slight dimple in the skin on a level with the interval between the third and fourth dorsal spines. Below this point the vertebral border of the scapula may be traced, running downward and outward, and thus diverging from the vertebral spines, to the inferior angle of the bone, which can be recognized, although covered by the Latissimus dorsi muscle. From this angle the axillary border can usually be traced through this thick muscular covering, forming, with the muscles, the posterior fold of the axilla. The coracoid process may be felt about an inch below the junction of the middle and outer third of the clavicle. Its position is indicated on the surface of the body by a slight depression which corresponds to the interval between the Pectoralis major and Deltoid muscles. When the arms are hanging by the side, the upper angle of the scapula corresponds to the upper border of the second rib or the interval between the first and second dorsal spines, the inferior angle to the upper border of the eighth rib or the interval between the seventh and eighth dorsal spines.

**Surgical Anatomy.**—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layer of muscles by which it is encased on both surfaces, and the elasticity of the ribs on which it rests. Fracture of the neck of the bone is also uncommon. The most frequent course of the fracture is from the supraspinous notch to the infraglenoid tubercle, and it derives its principal interest from its similitude to a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. A fracture of the neck external to, and not including, the coracoid process is said to occur, but it is exceedingly doubtful whether such an accident ever takes place. The acromion process is more frequently broken than any other part of the bone, and there is sometimes, in young subjects, a separation of the epiphysis. It is believed that many of the cases of supposed fracture of the acromion, with fibrous union, which have been found on post-mortem examination are really cases of imperfectly united epiphysis. Sir Astley Cooper believed that most fractures of this bone united by fibrous tissue, and the cause of this mode of union was the difficulty there was in keeping the fractured ends in constant apposition. The coracoid process is occasionally broken off, either from direct violence or perhaps, rarely, from muscular action.

Tumors of various kinds grow from the scapula. Of the innocent form of tumors probably the osteomata are the most common. When it grows from the venter of the scapula, as it
sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. This would appear to afford evidence that this portion of the bone is formed from membrane, and not, like the rest of the bone, from cartilage. Sarcomatous tumors sometimes grow from the scapula, and may necessitate removal of the bone, with or without amputation of the upper limb. The bone may be excised by a T incision, and, the flaps being reflected, the removal is commenced from the posterior or vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be at once secured.

THE ARM.

The Humerus.

The Humerus is the longest and largest bone of the upper extremity; it presents for examination a shaft and two extremities.

The Upper Extremity is the largest part of the bone; it presents a rounded head, joined to the shaft by a constricted portion, called the neck, and two other eminences, the greater and lesser tuberosities (Fig. 197).

The head, nearly hemispherical in form, is directed upward, inward, and a little backward, and articulates with the glenoid cavity of the scapula; its surface is smooth and coated with cartilage in the recent state. The circumference of its articular surface is slightly constricted, and is termed the anatomical neck, in contradistinction to the constriction which exists below the tuberosities. The latter is called the surgical neck, from its often being the seat of fracture. It should be remembered, however, that fracture of the anatomical neck does sometimes, though rarely, occur.

The anatomical neck is obliquely directed, forming an obtuse angle with the shaft. It is more distinctly marked in the lower half of its circumference than in the upper half, where it presents a narrow groove, separating the head from the tuberosities. Its circumference affords attachment to the capsular ligament and is perforated by numerous vascular foramina.

The greater tuberosity is situated on the outer side of the head and lesser tuberosity. Its upper surface is rounded and marked by three flat facets, separated by two slight ridges; the highest facet gives attachment to the tendon of the Supraspinatus; the middle one, to the Infraspinatus; the lowest facet and the shaft of the bone below it, to the Teres minor. The outer surface of the great tuberosity is convex, rough, and continuous with the outer side of the shaft.

The lesser tuberosity is more prominent, although smaller than the greater: it is situated in front of the head, and is directed inward and forward. Its summit presents a prominent facet for the insertion of the tendon of the Subscapularis muscle. The tuberosities are separated from one another by a deep groove, the bicipital groove, so called from its lodging the long tendon of the Biceps muscle, with which runs a branch of the anterior circumflex artery. It commences above between the two tuberosities, passes obliquely downward and a little inward, and terminates at the junction of the upper with the middle third of the bone. It is deep and narrow at the commencement, and becomes shallow and a little broader as it descends. Its borders are called, respectively, the external and internal bicipital ridges; to the former of which the name pectoral ridge is also, often applied. In the recent state this groove contains a prolongation of the synovial membrane of the shoulder-joint, and its floor receives that portion of the tendon of insertion of the Latissimus dorsi muscle which is reflected into it from the internal bicipital ridge.

The Shaft of the humerus is almost cylindrical in the upper half of its extent, prismatic and flattened below, and presents three borders and three surfaces for examination.

The anterior border runs from the front of the great tuberosity above to the

---

1 Though the head is nearly hemispherical in form, its margin, as Sir G. Humphry has shown, is by no means a true circle. Its greatest measurement is from the top of the bicipital groove in a direction downward, inward, and backward. Hence it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upward, outward, and forward.
coronoid depression below, separating the internal from the external surface. Its
upper part is very prominent and rough, and forms the outer lip of the bicipital groove. It is here often called the external bicipital ridge, and serves for the attachment of the tendon of the Pectoralis major. About its centre it forms the anterior boundary of the rough deltoid impression; below, it is smooth and rounded, affording attachment to the Brachialis anticus.

The external border runs from the back part of the greater tuberosity to the external condyle, and separates the external from the posterior surface. It is rounded and indistinctly marked in its upper half, serving for the attachment of the lower part of the insertion of the Teres minor, and below this of the external head of the Triceps muscle; its centre is traversed by a broad but shallow, oblique depression, the musculo-spiral groove; its lower part is marked by a prominent, rough margin, a little curved from behind forward, the external supracondylar ridge, which presents an anterior lip for the attachment of the Supinator longus above and Extensor carpi radialis longior below, a posterior lip for the Triceps, and an interstice for the attachment of the external intermuscular septum.

The internal border extends from the lesser tuberosity to the internal condyle. Its upper third is marked by a prominent ridge, forming the internal lip of the bicipital groove, and gives attachment to the tendon of the Teres major. About its centre is a rough ridge for the attachment of the Coraco-brachialis, and just below this is seen the entrance of the nutrient canal, directed downward. Sometimes there is a second canal higher up, which takes a similar direction. The inferior third of this border is raised into a slight ridge, the internal supracondylar ridge, which becomes very prominent below; it presents an anterior lip for the attachment of the Brachialis anticus, a posterior lip for the internal head of the Triceps, and an intermediate space for the internal intermuscular septum.

The external surface is directed outward above, where it is smooth, rounded, and covered by the Deltoid muscle; forward and outward below, where it is slightly concave from above downward, and gives origin to part of the Brachialis anticus muscle. About the middle of this surface is seen a rough, triangular impression for the insertion of the Deltoid muscle; and below it the musculo-spiral groove, directed obliquely from behind, forward and downward, and transmitting the musculo-spiral nerve and superior profunda artery.

The internal surface, less extensive than the external, is directed inward above, forward and inward below; at its upper part it is narrow and forms the floor of the bicipital groove; to it is attached the Latissimus dorsi. The middle part of this surface is slightly rough for the attachment of some of the fibres of the tendon of insertion of the Coraco-brachialis; its lower part is smooth, concave, and gives attachment to the Brachialis anticus muscle.

The posterior surface (Fig. 198) appears somewhat twisted, so that its upper part is directed a little inward, its lower part backward and a little outward. Nearly the whole of this surface is covered by the external and internal heads of the Triceps, the former of which is attached to its upper and outer part, the latter to its inner and back part, the two being separated by the musculo-spiral groove.

The Lower Extremity is flattened from before backward, and curved slightly forward; it terminates below in a broad, articular surface which is divided into two parts by a slight ridge. Projecting on either side are the external and inter

---

1 A small, hook-shaped process of bone, varying from \( \frac{1}{2} \) to \( \frac{3}{4} \) of an inch in length, is not unfrequently found projecting from the inner surface of the shaft of the humerus two inches above the internal condyle. It is curved downward, forward, and inward, and its pointed extremity is connected to the internal border, just above the inner condyle, by a ligament or fibrous band, completing an arch through which the median nerve and brachial artery pass when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery in cases of high division of the brachial. A well-marked groove is usually found behind the process in which the nerve and artery are lodged. This space is analogous to the supracondylid foramen in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region. A detailed account of this process is given by Dr. Struthers, in his Anatomical and Physiological Observations, p. 202. An accessory portion of the Coraco-brachialis muscle is frequently connected with this process, according to Mr. J. Wood, (Journal of Anat. and Phys., No. 3, Nov., 1869, p. 47).
nal condyles. The articular surface extends a little lower than the condyles, and is curved slightly forward, so as to occupy the more anterior part of the bone; its greatest breadth is in the transverse diameter, and it is obliquely directed, so that its inner extremity occupies a lower level than the outer. The outer portion of the articular surface presents a smooth, rounded eminence, which has received the name of the capitellum, or radial head of the humerus; it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone, not extending as far back as the other portion of the articular surface. On the inner side of this eminence is a shallow groove, in which is received the inner margin of the head of the radius. Above the front part of the capitellum is seen a slight depression which receives the anterior border of the head of the radius when the forearm is flexed. The inner portion of the articular surface, the trochlea, presents a deep depression between two well-marked borders. This surface is convex from before backward, concave from side to side, and occupies the anterior, lower, and posterior parts of the bone. The external border, less prominent than the internal, corresponds to the interval between the radius and the ulna. The internal border is thicker, more prominent, and consequently of greater length, than the external. The grooved portion of the articular surface fits accurately within the greater sigmoid cavity of the ulna: it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined obliquely from behind forward and from without inward. Above the front part of the trochlear surface is seen a smaller depression, the coronoid fossa, which receives the coronoid process of the ulna during flexion of the forearm. Above the back part of the trochlear surface is a deep, triangular depression, the olecranon fossa, in which is received the summit of the olecranon process in extension of the forearm. These fossae are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated, forming the supratrochlear foramen: their upper margins afford attachment to the anterior and posterior ligaments of the elbow-joint, and they are lined, in the recent state, by the synovial membrane of this articulation. The articular surfaces, in the recent state, are covered with a thin layer of cartilage. The external condyle is a small, tubercular eminence, less prominent than the internal, curved a little forward, and giving attachment to the external lateral ligament of the elbow-joint, and to a tendon common to the origin of some of the extensor and supi-

Fig. 195.—Left humerus. Posterior surface.
nator muscles. The internal condyle, larger and more prominent than the external, is directed a little backward: it gives attachment to the internal lateral ligament, to the Pronator radii teres, and to a tendon common to the origin of some of the flexor muscles of the forearm. The ulnar nerve runs in a groove at the back of the internal condyle, or between it and the olecranon process. These eminences are directly continuous above with the external and internal borders—i.e., the external and internal condyloid ridges. The great prominence of the inner one renders it more liable to fracture.

**Structure.**—The extremities consist of cancellous tissue, covered with a thin, compact layer; the shaft is composed of a cylinder of compact tissue, thicker at the centre than at the extremities, and hollowed out by a large medullary canal, which extends along its whole length.

**Development.**—By seven, or occasionally eight, centres (Fig. 199), one for the shaft, one for the head, one for the tuberosities, one for the radial head, one for the trochlear portion of the articular surface, and one for each condyle. The nucleus for the shaft appears near the centre of the bone in the eighth week, and soon extends toward the extremities. At birth the humerus is ossified nearly in its whole length, the extremities remaining cartilaginous. At the beginning of the second year ossification commences in the head of the bone, and during the third year the centre for the tuberosities makes its appearance, usually by a single ossific point, but sometimes, according to Béclard, by one for each tuberosity, that for the lesser being small and not appearing until the fifth year. By the sixth year the centres for the head and tuberosities have enlarged and become joined, so as to form a single large epiphysis.

The lower end of the humerus is developed in the following manner: At the end of the second year ossification commences in the radial portion of the articular surface, and from this point extends inward, so as to form the chief part of the articular end of the bone, the centre for the inner part of the articular surface not appearing until about the age of twelve. Ossification commences in the internal condyle about the fifth year, and in the external one not until about the thirteenth or fourteenth year. About sixteen or seventeen years the outer condyle and both portions of the articulating surface (having already joined) unite with the shaft; at eighteen years the inner condyle becomes joined; whilst the upper epiphysis, although the first formed, is not united until about the twentieth year.

**Articulations.**—With the glenoid cavity of the scapula and with the ulna and radius.

**Attachment of Muscles.**—To twenty-four: to the greater tuberosity, the Supraspinatus, Infraspinatus, and Teres minor; to the lesser tuberosity, the Subscapularis; to the external bicipital ridge, the Pectoralis major; to the internal bicipital ridge, the Teres major; to the bicipital groove, the Latissimus dorsi; to the shaft, the Deltoid, Coraco-brachialis, Brachialis anticus, external and internal heads of the Triceps; to the internal condyle, the Pronator radii teres, and common tendon of the Flexor carpi radialis, Palmaris longus, Flexor sublimis digitorum.
and Flexor carpi ulnaris; to the external condyloid ridge, the Supinator longus and Extensor carpi radialis longior; to the external condyle, the common tendon of the Extensor carpi radialis brevior, Extensor communis digitorum. Extensor minimi digiti, Extensor carpi ulnaris, and Supinator brevis; to the back of the external condyle, the Anconeus.

Surface Form.—The humerus is almost entirely clothed by the muscles which surround it, and the only parts of this bone which are strictly subcutaneous are small portions of the internal and external condyles. In addition to these, the tuberosities and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these the greater tuberosity forms the most prominent bony point of the shoulder, extending beyond the acromion process and covered by the Deltoid muscle. It influences materially the surface form of the shoulder. It is best felt while the arm is lying loosely by the side; if the arm be raised, it recedes from under the finger. The lesser tuberosity, directed forward and inward, is to be felt to the inner side of the greater tuberosity, just below the acromion-clavicular joint. Between the two tuberosities lies the bicipital groove. This can be defined by placing the finger and making firm pressure just internal to the greater tuberosity; then, by rotating the humerus, the groove will be felt to pass under the finger as the bone is rotated. With the arm abducted from the side, by pressing deeply in the axilla the lower part of the head of the bone is to be felt. On each side of the elbow-joint, and just above it, the internal and external condyles of the bone are to be felt. Of these the internal is the more prominent, but the ridge passing upward from it is less marked than the external, and, as a rule, is not to be felt. Occasionally, however, we find along this border the hook-shaped process mentioned above. The external condyle is most plainly to be seen during semiflexion of the forearm, and its position is indicated by a depression between the attachment of the adjacent muscles. From it is to be felt a strong bony ridge running up the outer border of the shaft of the bone. This is the external condyloid ridge; it is concave forward, and corresponds with the curved direction of the lower extremity of the humerus.

Surgical Anatomy.—There are several points of surgical interest connected with the humerus. First, as regards its development. The upper end, though the first to ossify, is the last to join the shaft, and the length of the bone is mainly due to growth from this upper epiphysis. Hence, in cases of amputation of the arm in young subjects the humerus continues to grow considerably, and the end of the bone which immediately after the operation was covered with a thick cushion of soft tissue, begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of a couple of inches or so of the bone, and even after this operation a recurrence of the conical stump may take place.

There are several points of surgical interest in connection with fractures. First, as regard their causation: the bone may be broken by direct or indirect violence like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other of this class of bone in the body. It is usually the shaft, just below the insertion of the Deltoid, which is thus broken. I have seen the accident happen from throwing a stone, and in an apparently healthy adult from cutting a piece of hard “cack tobacco” on a table. In this latter case the bone was no disease of the bone that could be discovered. Fractures of the upper end may take place through the anatomical neck, through the surgical neck, or separation of the greater tuberosity may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. These fractures are usually considered to be intracapsular, but they are probably partly within and partly without the capsule, as the lower part of the capsule is inserted some little distance below the anatomical neck, while the upper part is attached to it. They may be impacted or non-impacted. In most cases there is little or no displacement on account of the capsule, in whole or in part, remaining attached to the lower fragment. But occasionally a very remarkable alteration in position takes place; the upper fragment turns on its own axis, so that the cartilaginous surface of the head rests against the upper end of the lower fragment. When the fractured end is entirely separated from all its surroundings, its vascular supply must be entirely cut off, and one would expect it, theoretically, to necrose. But this must be exceedingly rare, for Gurlt was unable to find a single authenticated case recorded. Separation of the upper epiphysis of the humerus sometimes occurs in the young subject, and is marked by a characteristic deformity by which the lesion may be at once recognized. This consists in the presence of an abrupt projection at the front of the joint some short distance below the coracoid process, caused by the upper end of the lower fragment. In fractures of the shaft of the humerus the lesion may take place at any point, but appears to be more common in the lower than in the upper part of the bone. The points of interest in connection with these fractures are—(1) that the musculo-spiral nerve may be injured as it lies in the groove on the bone, or may become involved in the callus which is subsequently thrown out; and (2) the frequency of non-union. This is believed to be more common in the humerus than in any other bone, and various causes have been assigned for it. It would seem most probably to be due to the difficulty that there is in fixing the shoulder-joint and the upper fragment, and possibly also the elbow-joint and lower fragment also. Other causes which have been assigned for the non-union are: (1) that in attempting passive motion of the elbow-joint to overcome any rigidity which may exist, the movement does not take place at the articulation, but at the seat of fracture; or that the patient, in consequence of the rigidity of the elbow, in attempting
to flex or extend the forearm moves the fragment and not the joint. (2) The presence of small portions of muscular tissue between the broken ends. (3) Want of support to the elbow, so that the weight of the arm tends to drag the lower fragment away from the upper. An important distinction to make in fractures of the lower end of the humerus is between those that involve the joint and those which do not; the former always serious, as they may lead to impairment of the utility of the limb. They include the T-shaped fracture and oblique fractures which involve the articular surface. The fractures which do not involve the joint are the transverse above the condyles and detachment of one or other condyle.

Under the head of separation of the epiphysis two separate injuries have been described. One where the whole of the four ossific centres which form the lower extremity of the bone are separated from the shaft; and secondly, where the articular portion is alone separated, the two condyles remaining attached to the shaft of the bone. The epiphyseal line between the shaft and lower end runs across the bone just above the tips of the condyles, a point to be borne in mind in performing the operation of excision.

Tumors originating from the humerus are of frequent occurrence. A not uncommon place for a chondroma to grow from is the shaft of the bone somewhere in the neighborhood of the insertion of the deltoid. Sarcomata frequently grow from this bone.

THE FOREARM.

The Forearm is that portion of the upper extremity which is situated between the elbow and the wrist. It is composed of two bones, the ulna and radius.

The Ulna. (Figs. 200, 201), so called from its forming the elbow (ἀλένη), is a long bone, prismatic in form, placed at the inner side of the forearm, parallel with the radius. It is the larger and longer of the two bones. Its upper extremity, of great thickness and strength, forms a large part of the articulation of the elbow-joint; it diminishes in size from above downward, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an interarticular fibro-cartilage. It is divisible into a shaft and two extremities.

The Upper Extremity, the strongest part of the bone, presents for examination two large, curved processes, the Olecranon process and the Coronoid process; and two concave, articular cavities, the greater and lesser sigmoid cavities.

The Olecranon Process (ἀλένη, elbow; κρανίον, head) is a large, thick, curved eminence situated at the upper and back part of the ulna. It is curved forward at the summit so as to present a prominent tip, its base being contracted where it joins the shaft. This is the narrowest part of the upper end of the ulna, and, consequently, the most usual seat of fracture. The posterior surface of the olecranon, directed backward, is triangular, smooth, subcutaneous, and covered by a bursa. Its upper surface, directed upward, is of a quadrilateral form, marked behind by a rough impression for the attachment of the Triceps muscle; and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its anterior surface is smooth, concave, covered with cartilage in the recent state, and forms the upper and back part of the great sigmoid cavity. The lateral borders present a continuation of the same groove that was seen on the margin of the superior surface; they serve for the attachment of ligaments; viz. the back part of the internal lateral ligament internally, the posterior ligament externally. To the inner border is also attached a part of the Flexor carpi ulnaris, while to the outer border is attached the Anconeus.

The Coronoid Process (χορώπως, anything hooked like a crow's beak) is a rough, triangular eminence of bone which projects horizontally forward from the upper and front part of the ulna, forming the lower part of the great sigmoid cavity. Its base is continuous with the shaft, and of considerable strength; so much so that fracture of it is an accident of rare occurrence. Its apex is pointed, slightly curved upward, and received into the coronoid depression of the humerus in flexion of the forearm. Its upper surface is smooth, concave, and forms the lower part of the greater sigmoid cavity. The under surface is concave, and marked internally by a rough impression for the insertion of the Brachialis anticus. At the junction of this surface with the shaft is a rough eminence, the tubercle of

the ulna, for the attachment of the oblique ligament. Its outer surface presents a narrow, oblong, articular depression, the lesser sigmoid cavity. The inner surface, by its prominent, free margin, serves for the attachment of part of the internal lateral ligament. At the front part of this surface is a small, rounded eminence for the attachment of one head of the Flexor sublimis digitorum; behind the eminence, a depression for part of the origin of the Flexor profundus digitorum; and, descending from the eminence, a ridge which gives attachment to one head of the Pronator radii teres. Generally, the Flexor longus pollicis has an origin from the lower part of the coronoid process by a rounded bundle of muscular fibres.

The Greater Sigmoid Cavity, so called from its resemblance to the old shape of the Greek letter Σ, is a semilunar depression of large size, formed by the olecranon and coronoid processes, and serving for articulation with the trochlear surface of the humerus. About the middle of either lateral border of this cavity is a notch which contracts it somewhat, and serves to indicate the junction of the two processes of which it is formed. The cavity is concave from above downward, and divided into two lateral parts by a smooth, elevated ridge which runs from the summit of the olecranon to the tip of the coronoid process. Of these two portions, the internal is the larger, and is slightly concave transversely; the external portion is convex above, slightly concave below. The articular surface, in the recent state, is covered with a thin layer of cartilage.

The Lesser Sigmoid Cavity is a narrow, oblong, articular depression, placed on the outer side of the coronoid process, and serving for articulation with the head of the radius. It is concave from before backward, and its extremities, which are prominent, serve for the attachment of the orbicular ligament. In the recent state it is covered with a thin layer of cartilage.

The Shaft, at its upper part, is prismatic in form, and curved from behind forward and from without inward, so as to be convex behind and externally; its central part is quite straight; its lower part rounded, smooth, and bent a little outward; it tapers gradually from above downward, and presents for examination three borders and three surfaces.

The anterior border commences above at the prominent inner angle of the coronoid process, and terminates below in front of the styloid process. It is well marked above, smooth and rounded in the middle of its extent, and affords attachment to the Flexor profundus digitorum; its lower fourth, marked off from the rest of the border by the commencement of an oblique ridge on the anterior surface, serves for the attachment of the Pronator quadratus. It separates the anterior from the internal surface.

The posterior border commences above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and terminates below at the back part of the styloid process; it is well marked in the upper three-fourths, and gives attachment to an aponeurosis common to the Flexor carpi ulnaris, the Extensor carpi ulnaris, and the Flexor profundus digitorum muscles; its lower fourth is smooth and rounded. This border separates the internal from the posterior surface.

The external or interosseous border commences above by two lines, which converge one from each extremity of the lesser sigmoid cavity, enclosing between them a triangular space for the attachment of part of the Supinator brevis, and terminates below at the middle of the head of the ulna. Its two middle fourths are very prominent, its lower fourth is smooth and rounded. This border gives attachment to the interosseous membrane, except along its upper fourth, and separates the anterior from the posterior surface.

The anterior surface, much broader above than below, is concave in the upper three-fourths of its extent, and affords attachment to the Flexor profundus digitorum; its lower fourth, also concave, to the Pronator quadratus. The lower fourth is separated from the remaining portion of the bone by a prominent ridge, directed obliquely from above downward and inward; this ridge (the oblique or Pronator ridge) marks the extent of attachment of the Pronator quadratus above.

Fig. 201.—Bones of the left forearm. Posterior surface.
At the junction of the upper with the middle third of the bone is the nutrient canal directed obliquely upward and inward.

The posterior surface, directed backward and outward, is broad and concave above, somewhat narrower and convex in the middle of its course, narrow, smooth, and rounded below. It presents, above, an oblique ridge, which runs from the posterior extremity of the lesser sigmoid cavity, downward to the posterior border; the triangular surface above this ridge receives the insertion of the Anconeus muscle, whilst the ridge itself affords attachment to the Supinator brevis. The surface of bone below this is subdivided by a longitudinal ridge, sometimes called the perpendicular line, into two parts: the internal part is smooth, concave, and gives origin to (occasionally is merely covered by) the Extensor carpi ulnaris; the external portion, wider and rougher, gives attachment from above downward to part of the Supinator brevis, the Extensor ossis metacarpi pollicis, the Extensor longus pollicis, and the Extensor indicis muscles.

The internal surface is broad and concave above, narrow and convex below. It gives attachment by its upper three-fourths to the Flexor profundus digitorum muscle: its lower fourth is subcutaneous.

The Lower Extremity of the ulna is of small size, and excluded from the articulation of the wrist-joint. It presents for examination two eminences, the outer and larger of which is a rounded, articular eminence, termed the head of the ulna, the inner, narrower and more projecting, is a non-articular eminence, the styloid process. The head presents an articular facet, part of which, of an oval form, is directed downward, and articulates with the upper surface of the interarticular fibro-cartilage which separates it from the wrist-joint; the remaining portion, directed outward, is narrow, convex, and received into the sigmoid cavity of the radius. The styloid process projects from the inner and back part of the bone, and descends a little lower than the head, terminating in a rounded summit, which affords attachment to the internal lateral ligament of the wrist. The head is separated from the styloid process, by a depression for the attachment of the triangular interarticular fibro-cartilage; and behind, by a shallow groove for the passage of the tendon of the Extensor carpi ulnaris.

**Structure.**—Similar to that of the other long bones.

**Development.**—By three centres: one for the shaft, one for the inferior extremity, and one for the olecranon (Fig. 202). Ossification commences near the middle of the shaft about the eighth week, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year a separate osseous nucleus appears in the middle of the head, which soon extends into the styloid process. About the tenth year ossific matter appears in the olecranon near its extremity, the chief part of this process being formed from an extension of the shaft of the bone into it. At about the sixteenth year the upper epiphysis becomes joined, and at about the twentieth year the lower one.

**Articulations.**—With the humerus and radius.

**Attachment of Muscles.**—To sixteen: to the olecranon, the Triceps, Anconeus, and one head of the Flexor carpi ulnaris. To the coronoid process, the Brachialis anticus, Pronator radii teres, Flexor sublimis digitorum, and Flexor profundus digitorum; generally also the Flexor longus pollicis. To the shaft, the Flexor profundus digitorum, Pronator quadratus, Flexor carpi ulnaris, Extensor carpi ulnaris, Anconeus, Supinator brevis, Extensor ossis metacarpi pollicis, Extensor longus pollicis, and Extensor indicis.
Surface Form.—The most prominent part of the ulna on the surface of the body is the olecranon process, which can always be felt at the back of the elbow-joint. When the forearm is flexed the upper triangular surface can be felt, directed backward; during extension it recedes into the olecranon fossa, and the contracting fibres of the triceps prevent its being perceived. At the back of the olecranon is the smooth, triangular, subcutaneous surface, which below is continuous with the posterior border of the shaft of the bone; this is to be felt in every position of the joint. During extension the upper border of the olecranon is slightly above the level of the internal condyle, and the process itself is nearer to this condyle than the outer one. Running down the back of the forearm, from the apex of the triangular surface which forms the posterior surface of the olecranon, is a prominent ridge of bone, the posterior border of the ulna. This is to be felt throughout the entire length of the shaft of the bone from the olecranon above to the styloid process below. As it passes down the forearm it pursues a sinuous course and inclines to the inner side, so that, though it is situated in the middle of the back of the limb above, it is on the inner side of the wrist at its termination. It becomes rounded off in its lower third, and may be traced below to the small, subcutaneous surface of the styloid process. Internal to this border the lower fourth of the internal surface is to be felt. The styloid process is to be felt as a prominent tubercle of bone, continuous above with the posterior subcutaneous border of the ulna, and terminating below in a blunt apex, which lies a little internal and behind, but on a level with, the wrist-joint. The styloid process is best felt when the hand is in the same line as the bones of the forearm, and in a position midway between supination and pronation. If the forearm is pronated while the finger is placed on the process, it will be felt to recede, and another prominence of bone will appear just external and above it. This is the head of the ulna, which articulates with the lower end of the radius and the triangular interarticular fibro-cartilage, and now projects between the tendons of the Extensor carpi ulnaris and the Extensor minimi digiti muscles.

The Radius.

The Radius (radius, a ray, or spoke of a wheel) is situated on the outer side of the forearm, lying side by side with the ulna, which exceeds it in length and size. Its upper end is small, and forms only a small part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist. It is one of the long bones, prismatic in form, slightly curved longitudinally, and, like other long bones, has a shaft and two extremities.

The Upper Extremity presents a head, neck, and tuberosity. The head is of a cylindrical form, depressed on its upper surface into a shallow cup which articulates with the capitellum or radial head of the humerus. In the recent state it is covered with a layer of cartilage which is thinnest at its centre. Around the circumference of the head is a smooth, articular surface, broad internally where it articulates with the lesser sigmoid cavity of the ulna; narrow in the rest of its circumference, where it rotates within the orbicular ligament. It is coated with cartilage in the recent state. The head is supported on a round, smooth, and constricted portion of bone, called the neck, which presents, behind, a slight ridge, for the attachment of part of the Supinator brevis. Beneath the neck, at the inner and front aspect of the bone, is a rough eminence, the bicapital tuberosity. Its surface is divided into two parts by a vertical line—a posterior, rough portion, for the insertion of the tendon of the Biceps muscle; and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The Shaft of the bone is prismatic in form, narrower above than below, and slightly curved, so as to be convex outward. It presents three surfaces, separated by three borders.

The anterior border extends from the lower part of the tuberosity above to the anterior part of the base of the styloid process below. It separates the anterior from the external surface. Its upper third is very prominent; and from its oblique direction, downward and outward, has received the name of the oblique line of the radius. It gives attachment externally to the Supinator brevis, internally to the Flexor longus pollicis, and between these to the Flexor sublimis digitorum. The middle third of the anterior border is indistinct and rounded. Its lower fourth is sharp, prominent, affords attachment to the Pronator quadratus, and terminates in a small tubercle, into which is inserted the tendon of the Supinator longus.

The posterior border commences above at the back part of the neck of the
radius, and terminates below at the posterior part of the base of the styloid process; it separates the posterior from the external surface. It is indistinct above and below, but well marked in the middle third of the bone.

The internal or interosseous border commences above at the back part of the tuberosity, where it is rounded and indistinct, becomes sharp and prominent as it descends, and at its lower part divides into two ridges, which descend to the anterior and posterior margins of the sigmoid cavity. This border separates the anterior from the posterior surface, and has the interosseous membrane attached to it throughout the greater part of its extent.

The anterior surface is narrow and concave for its upper three-fourths, and gives attachment to the Flexor longus pollicis muscle; it is broad and flat for its lower fourth, and gives attachment to the Pronator quadratus. A prominent ridge limits the attachment of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the anterior ligament of the wrist-joint. At the junction of the upper and middle third of this surface is the nutrient foramen, which is directed obliquely upward.

The posterior surface is rounded, convex, and smooth in the upper third of its extent, and covered by the Supinator brevis muscle. Its middle third is broad, slightly concave, and gives attachment to the Extensor ossis metacarpi pollicis above, the Extensor brevis pollicis below. Its lower third is broad, convex, and covered by the tendons of the muscles, which subsequently run in the grooves on the lower end of the bone.

The external surface is rounded and convex throughout its entire extent. Its upper third gives attachment to the Supinator brevis muscle. About its centre is seen a rough ridge, for the insertion of the Pronator radii teres muscle. Its lower part is narrow, and covered by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis muscles.

The Lower Extremity of the radius is large, of quadrilateral form, and provided with two articular surfaces—one at the extremity, for articulation with the carpus, and one at the inner side of the bone, for articulation with the ulna. The carpal articular surface is of triangular form, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the external is large, of a triangular form, and articulates with the scaphoid bone; the inner, smaller and quadrilateral, articulates with the semilunar. The articular surface for the ulna is called the sigmoid cavity of the radius; it is narrow, concave, smooth, and articulates with the head of the ulna. The circumference of this end of the bone presents three surfaces—an anterior, external, and posterior. The anterior surface, rough and irregular, affords attachment to the anterior ligament of the wrist-joint. The external surface is prolonged obliquely downward into a strong, conical projection, the styloid process, which gives attachment by its base to the tendon of the Supinator longus, and by its apex to the external lateral ligament of the wrist-joint. The outer surface of this process is marked by a flat groove, which runs obliquely downward and forward, and gives passage to the tendons of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis. The posterior surface is convex, affords attachment to the posterior ligament of the wrist, and is marked by three grooves. Proceeding from without inward, the first groove is broad but shallow, and subdivided into two by a slightly elevated ridge: the outer of these two transmits the tendon of the Extensor carpi radialis longior, the inner the tendon of the Extensor carpi radialis brevior. The second, which is near the centre of the bone, is a deep but narrow groove, bounded on its outer side by a sharply-defined ridge; it is directed obliquely from above, downward and outward, and transmits the tendon of the Extensor longus pollicis. The third, lying most internally, is a broad groove, for the passage of the tendons of the Extensor indicis and Extensor communis digitorum.

Structure.—Similar to that of the other long bones.

Development (Fig. 203).—By three centres: one for the shaft and one for each extremity. That for the shaft makes its appearance near the centre of the bone.
soon after the development of the humerus commences. At birth the shaft is ossified, but the ends of the bone are cartilaginous. About the end of the second year ossification commences in the lower epiphysis and about the fifth year in the upper one. At the age of seventeen or eighteen the upper epiphysis becomes joined to the shaft, the lower epiphysis becoming united about the twentieth year.

Articulation.—With four bones: the humerus, ulna, scaphoid, and semilunar.

Attachment of Muscles.—To nine: to the tuberosity, the Biceps; to the oblique ridge, the Supinator brevis, Flexor sublimis digitorum, and Flexor longus pollicis; to the shaft (its anterior surface), the Flexor longus pollicis and Pronator quadratus; (its posterior surface), the Extensor ossis metacarpi pollicis and Extensor brevis pollicis; (its outer surface), the Pronator radii teres; and to the styloid process, the Supinator longus.

Surface Form.—Just below and a little in front of the posterior surface of the external condyle a part of the head of the radius may be felt, covered by the orbicular and external lateral ligaments. There is in this situation a little dimple in the skin, which is most visible when the arm is extended, and which marks the position of the head of the bone. If the finger is placed on this dimple and the forearm pronated and supinated, the head of the bone will be distinctly perceived rotating in the lesser sigmoid cavity. The upper half of the shaft of the radius cannot be felt, as it is surrounded by the fleshy bellies of the muscles arising from the external condyle. The lower half of the shaft is felt, though covered by tendons and muscles and not strictly subcutaneous. If traced downward, the shaft will be felt to terminate in a lozenge-shaped, convex surface on the outer side of the base of the styloid process. This is the only subcutaneous part of the bone, and from its lower extremity the apex of the styloid process will be felt bending inward toward the wrist. About the middle of the posterior aspect of the lower extremity of the bone is a well-marked ridge, best perceived when the hand is slightly flexed on the wrist. It bounds the oblique groove on the posterior surface of the bone, through which the tendon of the Extensor longus pollicis runs, and serves to keep that tendon in its place.

Surgical Anatomy.—The two bones of the forearm are more often broken together than is either the radius or ulna separately. It is therefore convenient to consider the fractures of these two bones together in the first instance, and subsequently to mention the principal fractures which take place in each bone individually. These fractures may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius generally alone gives way, though both bones may suffer. The fracture from indirect force generally takes place somewhere about the middle of the bones; fracture from direct violence may occur at any part, more often, however, in the lower half of the bone. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency that there is for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other, and therefore diminishes the risk of the bones becoming united across the interosseous membrane. The splints, anterior and posterior, which are applied in these cases should be rather wider than the limb, so as to prevent any lateral pressure on the bones. For in these cases there is a greater liability to gangrene from the pressure of the splints than in other parts of the body. This is no doubt due principally to two causes: (1) the flexion of the forearm compressing to a certain extent the brachial artery and retarding the flow of blood to the limb; and (2) the superficial position of the two main arteries of the forearm in a part of their course, and their liability to be compressed by the splints. The special fractures of the ulna are—(1) Fracture of the olecranon. This may be caused by direct violence, falls on the elbow with the forearm flexed, or by muscular action by the sudden contraction of the triceps. The most common place for the fracture to occur is at the constricted portion where the olecranon joins the shaft of the bone, and the fracture may be either transverse or oblique; but any part may be broken, even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. The displacement is sometimes very slight, owing to the fibrous structures around the process not being torn. (2) Fracture of the coronoid process some-
times occurs as a complication of dislocation backward of the bones of the forearm, but it is
doubtful if it ever occurs as an uncomplicated injury. (3) Fractures of the shaft of the ulna
may occur at any part, but usually take place at the middle of the bone or a little below it.
They are almost always the result of direct violence. (4) The styloid process may be knocked
off by direct violence. Fractures of the radius consist of—(1) Fracture of the head of the bone;
this generally occurs in conjunction with some other lesion, but may occur as an uncomplicated
injury. (2) Fracture of the neck may also take place, but is generally complicated with other
injury. (3) Fractures of the shaft of the radius are very common, and may take place at any
part of the bone. They may take place from either direct or indirect violence. (4) The most
important fracture of the radius is that of the lower end (Colle's fracture). The fracture is
transverse, and generally takes place about an inch from the lower extremity. It is caused by
falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the
female than the male. In consequence of the manner in which the fracture is caused, the upper
fragment becomes driven into the lower, and impaction is the result; or else the lower fragment
becomes split up into two or more pieces, so that no fixation occurs. Separation of the lower
evertheless of the radius may take place in the young. This injury and Colle's fracture may be
distinguished from other injuries in this neighborhood—especially dislocation, with which it is
liable to be confounded—by observing the relative positions of the styloid processes of the ulna
and radius. In the natural condition of parts, with the arm hanging by the side, the styloid pro-
cess of the radius is on a lower level than that of the ulna; that is to say, nearer the ground.
After fracture or separation of the epiphysis this process is on the same or higher level than that
of the ulna, whereas it would be unaltered in position in dislocation.

THE HAND.

The skeleton of the Hand is subdivided into three segments—the Carpus or
wrist-bones; the Metacarpus or bones of the palm; and the Phalanges or bones
of the fingers.

The Carpus.

The bones of the Carpus (καρπός, the wrist), eight in number, are arranged in
two rows. Those of the upper row, enumerated from the radial to the ulnar
side, are the scaphoid, semilunar, cuneiform, and pisiform; those of the lower
row, enumerated in the same order, are the trapezium, trapezoid, os magnum, and
unciform.

Common Characters of the Carpal Bones.

Each bone (excepting the pisiform) presents six surfaces. Of these the anterior
or palmar and the posterior or dorsal are rough for ligamentous attachment,
the dorsal surface being the broader, except in the scaphoid and semilunar. The
superior or proximal and inferior or distal are articular, the superior generally
convex, the inferior concave; and the internal and external are also articular when
in contact with contiguous bones, otherwise rough and tubercular. The structure
in all is similar, consisting of cancellous tissue enclosed in a layer of compact bone.
Each bone is also developed from a single centre of ossification.

Bones of the Upper Row (Figs. 204, 205).

The Scaphoid (σκαφος, a boat; σκάφος, like) is the largest bone of the first row.
It has received its name from its fancied resemblance to a boat, being broad
at one end, and narrowed like a prow at the opposite. It is situated at the
upper and outer part of the carpus, its long axis being from above downward,
outward and forward. The superior surface is convex, smooth, of triangular
shape, and articulates with the lower end of the radius. The inferior surface,
directed downward, outward, and backward, is smooth, convex, also triangular,
and divided by a slight ridge into two parts, the external of which articulates
with the trapezium, the inner with the trapezoid. The posterior or dorsal surface
presents a narrow, rough groove, which runs the entire breadth of the bone and
serves for the attachment of ligaments. The anterior or palmar surface is concave
above, and elevated at its lower and outer part into a prominent, rounded tubercle,
which projects forward from the front of the carpus and gives attachment to
the anterior annular ligament of the wrist. The external surface is rough and
narrow, and gives attachment to the external lateral ligament of the wrist. The
internal surface presents two articular facets: of these, the superior or smaller one is flattened, of semilunar form, and articulates with the semilunar; the inferior or larger is concave, forming, with the semilunar bone, a concavity for the head of the os magnum.
To ascertain to which side the bone belongs, hold it with the superior or radial convex, articular, surface upward, and the posterior surface—i. e. the narrow, non-articular, grooved surface—toward you. The tubercle on the outer surface points to the side to which the bone belongs.  

Articulations.—With five bones: the radius above, trapezium and trapezoid below, os magnum and semilunar internally.

The Lunar or Semilunar (semi, half; luna, moon) bone may be distinguished by its deep concavity and crescentic outline. It is situated in the centre of the upper row of the carpus, between the scaphoid and cuneiform. The superior surface, convex, smooth, and bounded by four edges, articulates with the radius. The inferior surface is deeply concave, and of greater extent from before backward than transversely: it articulates with the head of the os magnum and by a long, narrow facet (separated by a ridge from the general surface) with the unciform bone. The anterior or palmar and posterior or dorsal surfaces are rough, for the attachment of ligaments, the former being the broader and of somewhat rounded form. The external surface presents a narrow, flattened, semilunar facet for articulation with the scaphoid. The internal surface is marked by a smooth, quadrilateral facet, for articulation with the cuneiform.

Hold it with the convex articular surface for the radius upward, and the narrowest non-articular surface toward you. The semilunar facet for the scaphoid will be on the side to which the bone belongs.

Articulations.—With five bones: the radius above, os magnum and unciform below, scaphoid and cuneiform on either side.

The Cuneiform (cuneus, a wedge; forma, likeness) may be distinguished by its pyramidal shape (os pyramidale), and by its having an oval, isolated facet for articulation with the pisiform bone. It is situated at the upper and inner side of the carpus. The superior surface presents an internal, rough, non-articular portion, and an external or articular portion, which is convex, smooth, and articulates with the triangular interarticular fibro-cartilage of the wrist. The inferior surface, directed outward, is concave, sinusously curved, and smooth for articulation with the unciform. The posterior or dorsal surface is rough, for the attachment of ligaments. The anterior or palmar surface presents, at its inner side, an oval facet, for articulation with the pisiform; and is rough externally, for ligamentous attachment. The external surface, the base of the pyramid, is marked by a flat, quadrilateral, smooth facet, for articulation with the semilunar. The internal surface, the summit of the pyramid, is pointed and roughened, for the attachment of the internal lateral ligament of the wrist.

Hold the bone with the surface supporting the pisiform facet away from you, and the concavo-convex surface for the unciform downward. The base of the wedge (i. e. the broad end of the bone) will be on the side to which it belongs.

Articulations.—With three bones: the semilunar externally, the pisiform in front, the unciform below; and with the triangular, interarticular fibro-cartilage which separates it from the lower end of the ulna.

The Pisiform (pisum, a pea; forma, likeness) may be known by its small size and by its presenting a single articular facet. It is situated at the anterior and inner side of the carpus, is nearly circular in form, and presents on its posterior surface a smooth, oval facet, for articulation with the cuneiform. This facet approaches the superior, but not the inferior, border of the bone. The anterior or palmar surface is rounded and rough, and gives attachment to the anterior annular ligament and to the Flexor carpi ulnaris and Abductor minimi digiti muscles. The outer and inner surfaces are also rough, the former being convex, the latter usually concave.

Hold the bone with the posterior surface—that which presents the articular facet—toward you. The tubercle on the outer surface points to the side to which the bone belongs.  

1 In these directions each bone is supposed to be placed in its natural position—that is, such a position as it would occupy when the arm is hanging by the side, the forearm in a position of supination, the thumb being directed outward, and the palm of the hand looking forward.
facet—toward you, in such a manner that the faceted portion of the surface is uppermost. The outer, convex surface will point to the side to which it belongs.

**Articulations.**—With one bone, the cuneiform.

**Attachment of Muscles.**—To two: the Flexor carpi ulnaris and Abductor minimi digitii; and to the anterior annular ligament.
Bones of the Lower Row (Figs. 204, 205).

The Trapezium (τραπέζιον, a table) is of very irregular form. It may be distinguished by a deep groove, for the tendon of the Flexor carpi radialis muscle. It is situated at the external and inferior part of the carpus, between the scaphoid and first metacarpal bone. The superior surface, concave and smooth, is directed upward and inward, and articulates with the scaphoid. The inferior surface, directed downward and inward, is oval, concave from side to side, convex from before backward, so as to form a saddle-shaped surface, for articulation with the base of the first metacarpal bone. The anterior or palmar surface is narrow and rough. At its upper part is a deep groove running from above obliquely downward and inward; it transmits the tendon of the Flexor carpi radialis, and is bounded externally by a prominent ridge, the oblique ridge of the trapezium. This surface gives attachment to the Abductor pollicis, Flexor ossis metacarpi pollicis, and Flexor brevis pollicis muscles, and the anterior annular ligament. The posterior or dorsal surface is rough. The external surface is also broad and rough, for the attachment of ligaments. The internal surface presents two articular facets: the upper one, large and concave, articulates with the trapezoid; the lower one, narrow and flattened, with the base of the second metacarpal bone.

Hold the bone with the saddle-shaped surface downward and the grooved surface away from you. The prominent, rough, non-articular surface points to the side to which the bone belongs.

Articulations.—With four bones: the scaphoid above, the trapezoid and second metacarpal bones internally, the first metacarpal below.

Attachment of Muscles.—Abductor pollicis, Flexor ossis metacarpi pollicis, and part of the Flexor brevis pollicis.

The Trapezoide is the smallest bone in the second row. It may be known by its wedge-shaped form, the broad end of the wedge forming the dorsal, the narrow end the palmar, surface, and by its having four articular surfaces touching each other and separated by sharp edges. The superior surface, quadrilateral in form, smooth, and slightly concave, articulates with the scaphoid. The inferior surface articulates with the upper end of the second metacarpal bone; it is convex from side to side, concave from before backward, and subdivided by an elevated ridge into two unequal lateral facets. The posterior or dorsal and anterior or palmar surfaces are rough, for the attachment of ligaments, the former being the larger of the two. The external surface, convex and smooth, articulates with the trapezium. The internal surface is concave and smooth in front, for articulation with the os magnum; rough behind, for the attachment of an intersosseous ligament.

Hold the bone with the larger, non-articular surface toward you, and the smooth, quadrilateral articular surface upward. The convex, articular surface will point to the side to which the bone belongs. 1

Articulations.—With four bones: the scaphoid above, second metacarpal bone below, trapezium externally, os magnum internally.

The Os Magnum is the largest bone of the carpus, and occupies the centre of the wrist. It presents, above, a rounded portion or head, which is received into the concavity formed by the scaphoid and semilunar bones; a constricted portion or neck; and, below, the body. The superior surface is rounded, smooth, and articulates with the semilunar. The inferior surface is divided by two ridges into three facets, for articulation with the second, third, and fourth metacarpal bones, that for the third (the middle facet) being the largest of the three. The posterior or dorsal surface is broad and rough; the anterior or palmar, narrow, rounded, and also rough, for the attachment of ligaments. The external surface articulates

1 Occasionally in a badly marked bone there is some difficulty in ascertaining to which side the bone belongs; the following method will sometimes be found useful: Hold the bone with its broader, non-articular surface upward, so that its sloping border is directed toward you. The border will slope to the side to which the bone belongs.
with the trapezoid by a small facet at its anterior inferior angle, behind which is
a rough depression for the attachment of an interosseous ligament. Above this
is a deep and rough groove, which forms part of the neck and serves for the
attachment of ligaments, bounded superiorly by a smooth, convex surface, for
articulation with the scaphoid. The internal surface articulates with the unciform
by a smooth, concave, oblong facet which occupies its posterior and superior
parts, and is rough in front, for the attachment of an interosseous ligament.

Hold the bone with the broader, non-articular surface toward you, and the
head upward. The small, articular facet at the anterior inferior angle of the
external surface will point to the side to which the bone belongs.

Articulations.—With seven bones: the scaphoid and semilunar above; the
second, third, and fourth metacarpal below; the trapezoid on the radial side; and
the unciform on the ulnar side.

Attachment of Muscles.—Part of the Adductor obliquus pollicis.

The Unciform (uncus, a hook; forma, likeness) may be readily distinguished
by its wedge-shaped form and the hook-like process that projects from its palmar
surface. It is situated at the inner and lower angle of the carpus, with its base
downward, resting on the two inner metacarpal bones, and its apex directed
upward and outward. The superior surface, the apex of the wedge, is narrow,
convex, smooth, and articulates with the semilunar. The inferior surface articu-
lates with the fourth and fifth metacarpal bones, the concave surface for each
being separated by a ridge which runs from before backward. The posterior or
dorsal surface is triangular and rough, for ligamentous attachment. The anterior
or palmar surface presents, at its lower and inner side, a curved, hook-like pro-
cess of bone, the unciform process, directed from the palmar surface forward and
outward. It gives attachment by its apex to the annular ligament; by its inner
surface to the Flexor brevis minimi digitii and the Flexor ossis metacarpi minimi
digitii; and is grooved on its outer side, for the passage of the Flexor tendons
into the palm of the hand. This is one of the four eminences on the front of the
carpus to which the anterior annular ligament is attached, the others being the
pisiform internally, the oblique ridge of the trapezium and the tuberosity of the
scaphoid externally. The internal surface articulates with the cuneiform by an
oblong facet cut obliquely from above, downward and inward. The external sur-
face articulates with the os magnum by its upper and posterior part, the remaining
portion being rough, for the attachment of ligaments.

Hold the bone with the hooked process away from you, and the articular sur-
face, divided into two parts, for the metacarpal bones, downward. The concavity
of the process will be on the side to which the bone belongs.

Articulations.—With five bones: the semilunar above, the fourth and fifth
metacarpal below, the cuneiform externally, the os magnum externally.

Attachment of Muscles.—To three: the Flexor brevis minimi digitii, the Flexor
ossis metacarpi minimi digitii, the Flexor carpi ulnaris; and to the anterior annular
ligament.

The Metacarpus.

The Metacarpal Bones are five in number: they are long, cylindrical bones,
presenting for examination a shaft and two extremities.

Common Characters of the Metacarpal Bones.

The Shaft is prismoid in form and curved longitudinally, so as to be convex in
the longitudinal direction behind, concave in front. It presents three surfaces:
two lateral and one posterior. The lateral surfaces are concave, for the attach-
ment of the Interossei muscles, and separated from one another by a prominent
line. The posterior or dorsal surface presents in its distal half a smooth,
triangular, flattened area which is covered, in the recent state, by the tendons of
the Extensor muscles. This triangular surface is bounded by two lines, which
commence in small tubercles situated on the dorsal aspect of either side of the
digital extremity, and, running backward, converge to meet together a little behind the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two lateral, sloping surfaces for the attachment of the Dorsal interossei muscles.\(^1\) To the tubercles on the digital extremities are attached the lateral ligaments of the metacarpo-phalangeal joints.

The **carpal extremity**, or base, is of a cuboidal form, and broader behind than in front; it articulates above with the carpus, and on each side with the adjoining metacarpal bones; its **dorsal and palmar surfaces** are rough, for the attachment of tendons and ligaments.

The **digital extremity**, or head, presents an oblong surface, flattened at each side; it articulates with the proximal phalanx; it is broader and extends farther forward in front than behind, and is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the lateral ligament of the metacarpo-phalangeal joint. The **posterior surface**, broad and flat, supports the Extensor tendons; the **anterior surface** is grooved in the middle line for the passage of the Flexor tendons, and marked on each side by an articular eminence continuous with the terminal articular surface.

### Peculiar Characters of the Metacarpal Bones.

The **metacarpal bone of the thumb** is shorter and wider than the rest, diverges to a greater degree from the carpus, and its **palmar surface** is directed inward toward the palm. The **shaft** is flattened and broad on its dorsal aspect, and does not present the ridge which is found on the other metacarpal bones; it is concave from before backward on its palmar surface. The **carpal extremity**, or base, presents a concavo-convex surface, for articulation with the trapezium; it has no lateral facets. The **digital extremity** is less convex than that of the other metacarpal bones, broader from side to side than from before backward, and terminates anteriorly in a small articular, eminence on each side, over which play two sesamoid bones.

The side to which this bone belongs may be known by observing the little prominence which is situated on the outer or radial side of its posterior surface just above the base, for the tendon of the Extensor ossis metacarpi pollicis. If the bone is held with the palmar surface upward and the base toward the student, the prominence will point to the side to which the bone belongs. Another means by which the side to which the bone belongs may be ascertained is by holding it in the position it occupies in the hand, with the carpal extremity upward and the dorsal surface backward; the narrower, radial border will point to the side to which it belongs.

The **metacarpal bone of the index finger** is the longest and its base the largest of the other four. Its **carpal extremity** is prolonged upward and inward, forming a prominent ridge. The dorsal and palmar surfaces of this extremity are rough, for the attachment of tendons and ligaments. It presents four articular facets: three on the upper aspect of the base: the middle one of the three is the largest, concave from side to side, convex from before backward, for articulation with the trapezoid; the external one is a small, flat, quadrilateral facet, for articulation with the trapezium; the internal one on the summit of the ridge is long and narrow, for articulation with the os magnum. The fourth facet is on the inner or ulnar side of the extremity of the bone, and is for articulation with the third metacarpal bone.

The side to which this bone belongs is indicated by the absence of the lateral facet on the outer (radial) side of its base, so that if the bone is placed with its base toward the student and the palmar surface upward, the side on which there is **no** lateral facet will be that to which it belongs.

---

\(^1\) By these sloping surfaces the metacarpal bones of the hand may be at once differentiated from those of the foot.
The metacarpal bone of the middle finger is a little smaller than the preceding: it presents a pyramidal eminence (the styloid process) on the radial side of its base (dorsal aspect) which extends upward behind the os magnum. The carpal, articular facet is concave behind, flat in front, and articulates with the os magnum. On the radial side is a smooth, concave facet, for articulation with the second metacarpal bone, and on the ulnar side two small, oval facets, for articulation with the fourth metacarpal.

The side to which this bone belongs is easily recognized by the styloid process on the radial side of its base. With the palmar surface uppermost and the base toward the student, this process points toward the side to which the bone belongs.

The metacarpal bone of the ring finger is shorter and smaller than the preceding, and its base small and quadrilateral; the carpal surface of the base presenting two facets, for articulation with the unciform and os magnum. On the radial side are two oval facets, for articulation with the third metacarpal bone; and on the ulnar side a single concave facet, for the fifth metacarpal.

If this bone is placed with the base toward the student and the palmar surface upward, the radial side of the base, which has two facets for articulation with the third metacarpal bone, will be on the side to which it belongs. If, as sometimes happens in badly-marked bones, one of these facets is indistinguishable, the side may be known by selecting the surface on which the larger articular facet is present. This facet is for the fifth metacarpal bone, and would therefore be situated on the ulnar side; that is, the one to which the bone does not belong.

The metacarpal bone of the little finger presents on its base one facet, which is concavo-convex, and which articulates with the unciform bone, and one lateral, articular facet, which articulates with the fourth metacarpal bone. On its ulnar side is a prominent tubercle, for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the shaft is marked by an oblique ridge which extends from near the ulnar side of the upper extremity to the radial side of the lower. The outer division of this surface serves for the attachment of the Fourth dorsal interosseous muscle; the inner division is smooth and covered by the Extensor tendons of the little finger.

If this bone is placed with its base toward the student and its palmar surface upward, the side of the head which has a lateral facet will be that to which the bone belongs.

Articulations.—Besides the phalangeal articulations, the first metacarpal bone articulates with the trapezium; the second with the trapezium, trapezoid, os magnum, and third metacarpal bones; the third with the os magnum and second and fourth metacarpal bones; the fourth with the os magnum, unciform, and third and fifth metacarpal bones; and the fifth with the unciform and fourth metacarpal.

The first has no lateral facets on its carpal extremity; the second has no lateral facet on its radial side, but one on its ulnar side; the third has one on its radial and two on its ulnar side; the fourth has two on its radial and one on its ulnar side; and the fifth has only one on its radial side.

Attachment of Muscles.—To the metacarpal bone of the thumb, four: the Flexor ossis metacarpi pollicis, Flexor brevis pollicis, Extensor ossis metacarpi pollicis, and First dorsal interosseous. To the second metacarpal bone, six: the Flexor carpi radialis, Extensor carpi radialis longior, Adductor obliquus pollicis, First and Second dorsal interosseous, and First palmar interosseous. To the third, six: the Extensor carpi radialis brevior, Flexor carpi radialis, Adductor transversus pollicis, Adductor obliquus pollicis, and Second and Third dorsal interosseous. To the fourth, three: the Third and Fourth dorsal and Second palmar interosseous. To the fifth, five: the Extensor carpi ulnaris, Flexor carpi ulnaris, Flexor ossis metacarpi minimi digitii, Fourth dorsal and Third palmar interosseous.
The Phalanges.

The Phalanges (internodia) are the bones of the fingers; they are fourteen in number, three for each finger, and two for the thumb. They are long bones, and present for examination a shaft and two extremities. The shaft tapers from above downward, is convex posteriorly, concave in front from above downward, flat from side to side, and marked laterally by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. The metacarpal extremity, or base, in the first row presents an oval, concave, articular surface, broader from side to side than from before backward; and the same extremity in the other two rows, a double concavity, separated by a longitudinal median ridge, extending from before backward. The digital extremities are smaller than the others, and terminate, in the first and second rows, in two small, lateral condyles, separated by a slight groove; the articular surface being prolonged farther forward on the palmar than on the dorsal surface, especially in the first row.

The Ungual Phalanges are convex on their dorsal, flat on their palmar, surfaces; they are recognized by their small size and by a roughened, elevated surface of a horseshoe form on the palmar aspect of their ungual extremity, which serves to support the sensitive pulp of the finger.

Articulations.—The first row, with the metacarpal bones and the second row of phalanges; the second row, with the first and third; the third, with the second row.

Attachment of Muscles.—To the base of the first phalanx of the thumb, five muscles: the Extensor brevis pollicis, Flexor brevis pollicis, Abductor pollicis, Adductor transversus and obliquus pollicis. To the second phalanx, two: the Flexor longus pollicis and the Extensor longus pollicis. To the base of the first phalanx of the index finger, the First dorsal and the First palmar interosseous; to that of the middle finger, the Second and Third dorsal interosseous; to that of the ring finger, the Fourth dorsal and the Second palmar interosseous; and to that of the little finger, the Third palmar interosseous, the Flexor brevis minimi digiti, and Abductor minimi digiti. To the second phalanges, the Flexor sublimis digitorum, Extensor communis digitorum, and, in addition, the Extensor indicis to the index finger, the Extensor minimi digiti to the little finger. To the third phalanges, the Flexor profundus digitorum and Extensor communis digitorum.

Surface Form.—On the front of the wrist are two subcutaneous eminences, one on the radial side, the larger and flatter, due to the tuberosity of the scaphoid and the ridge on the trapezium; the other, on the ulnar side, caused by the pisiform bone. The tuberole of the scaphoid is to be felt just below and in front of the apex of the styloid process of the radius. It is best perceived by extending the hand on the forearm. Immediately below is to be felt another prominence, better marked than the tuberole; this is the ridge on the trapezium which gives attachment to some of the short muscles of the thumb. On the inner side of the front of the wrist the pisiform bone is to be felt, forming a small but prominent projection in this situation. It is some distance below the styloid process of the ulna, and may be said to be just below the level of the styloid process of the radius. The rest of the front of the carpus is covered by tendons and the annular ligament, and entirely concealed, with the exception of the hooked process of the unciform, which can only be made out with difficulty. The back of the carpus is convex and covered by the Extensor tendons, so that none of the posterior surfaces of the bones are to be felt, with the exception of the euneiform on the inner side. Below the carpus the dorsal surfaces of the metacarpal bones, except the fifth, are covered by tendons, and are scarcely visible except in very thin hands. The dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length, and is plainly to be perceived and felt. In addition to this, slightly external to the middle line of the hand, is a prominence, frequently well marked, but occasionally indistinct, formed by the base of the metacarpal of the middle finger. The heads of the metacarpal bones are plainly to be felt and seen, rounded in contour and standing out in bold relief under the skin, when the fist is clenched. It should be borne in mind that when the fingers are flexed on the hand, the articular surfaces of the first phalanges glide off the heads of the metacarpal bones on to their anterior surfaces, so that the heads of these bones form the prominence of the knuckles and receive the force of any blow which may be given. The head of the third metacarpal bone is the most prominent, and receives the greater part of the shock of the blow. This bone articulates with the os magnum, so that the concussion is carried through this bone to the scaphoid and semilunar, with which the head of the os magnum articulates, and by these bones is transferred to the radius, along which it may be carried to the capitellum of the humerus. The enlarged extremities of the phalanges are to be plainly felt: they form the
Development of the Bones of the Hand.

The Carpal Bones are each developed by a single centre. At birth they are all cartilaginous. Ossification proceeds in the following order (Fig. 206): In the

The os magnum and unciform an ossific point appears during the first year, the former preceding the latter; in the cuneiform, at the third year; in the trapezium and semilunar, at the fifth year, the former preceding the latter; in the scaphoid, at
the sixth year; in the trapezoid, during the eighth year; and in the pisiform, about the twelfth year.

The Metacarpal Bones are each developed by two centres: one for the shaft and one for the digital extremity for the four inner metacarpal bones; one for the shaft and one for the base for the metacarpal bone of the thumb, which in this respect resembles the phalanges.1 Ossification commences in the centre of the shaft about the eighth or ninth week, and gradually proceeds to either end of the bone: about the third year the digital extremities of the four inner metacarpal bones and the base of the first metacarpal begin to ossify, and they unite about the twentieth year.

The Phalanges are each developed by two centres: one for the shaft and one for the base. Ossification commences in the shaft, in all three rows, at about the eighth week, and gradually involves the whole of the bone excepting the upper extremity. Ossification of the base commences in the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united, in each row, between the eighteenth and twentieth years.

THE LOWER EXTREMITY.

The Lower Extremity consists of three segments, the thigh, leg, and foot, which correspond to the arm, forearm, and hand in the upper extremity. It is connected to the trunk through the os innominatum, or hip-bone, which forms the pelvic girdle.

THE HIP.

The Os Innominatum.

The Os Innominatum (in, not; nomino, I name), or nameless bone, so called from bearing no resemblance to any known object, is a large, irregularly-shaped, flat bone, constricted in the centre and expanded above and below. With its fellow of the opposite side it forms the sides and anterior wall of the pelvic cavity. In young subjects it consists of three separate parts, which meet and form the large, cup-like cavity situated near the middle of the outer surface of the bone; and, although in the adult these have become united, it is usual to describe the bone as divisible into three portions—the ilium, the ischium, and the os pubis.

The ilium, so called from its supporting the flank (ilia), is the superior, broad and expanded portion which runs upward from the upper and back part of the acetabulum and forms the prominence of the hip.

The ischium (ischiov, the hip) is the inferior and strongest portion of the bone; it proceeds downward from the acetabulum, expands into a large tuberosity, and then, curving upward, forms with the descending ramus of the os pubis, a large aperture, the obturator foramen.

The os pubis is that portion which runs horizontally inward from the inner side of the acetabulum for about two inches, then makes a sudden bend, and descends for about one inch: it forms the front of the pelvis, supports the external organs of generation, and has received its name from the skin over it being covered with hair.

The Ilium presents for examination two surfaces, an external and an internal; a crest, and two borders, an anterior and a posterior.

External Surface or Dorsum of the Ilium (Fig. 207).—The back part of this surface is directed backward, downward, and outward; its front part, forward, downward, and outward. It is smooth, convex in front, deeply concave behind; bounded above by the crest, below by the upper border of the acetabulum; in front and behind by the anterior and posterior borders. This surface is crossed in an arched direction by three semicircular lines—the superior, middle, and inferior gluteal lines. The superior gluteal line, the shortest of the three, commences at

---

1 Allan Thomson has demonstrated the fact that the first metacarpal bone is often developed from three centres; that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis, visible at the age of seven or eight years. He also states that there are traces of a proximal epiphysis in the second metacarpal bone.—Journal of Anatomy, 1869.
the crest, about two inches in front of its posterior extremity; it is at first distinctly marked, but as it passes downward and outward to the upper part of the great sacro-sciatic notch, where it terminates, it becomes less marked, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and affords attachment to part of the Gluteus maximus; the lower part is smooth and has no muscular fibres attached to it. The middle gluteal line, the longest of the three, commences at the crest, about an inch behind its anterior extremity, and, taking a curved direction downward and backward, terminates at the upper part of the great sacro-sciatic notch. The base between the superior and middle curved lines and the crest is concave, and affords attachment to the Gluteus medius muscle. Near the central part of this line may often be observed the orifice of a nutrient foramen. The inferior gluteal line, the least distinct of the three, commences in front at the upper part of the anterior inferior spinous process, and,
taking a curved direction backward and downward, terminates at the middle of the great sacro-sciatic notch. The surface of bone included between the middle and inferior curved lines is concave from above downward, convex from before backward, and affords attachment to the Gluteus minimus muscle. Beneath the inferior curved line, and corresponding to the upper part of the acetabulum, is a roughened surface (sometimes a depression), to which is attached the reflected tendon of the Rectus femoris muscle.

The Internal Surface (Fig. 208) of the ilium is bounded above by the crest; below it is continuous with the pelvic surface of the os pubis and ischium, a faint line only indicating the place of union; and before and behind it is bounded by the anterior and posterior borders. It presents anteriorly a large, smooth, concave surface, called the internal iliac fossa, or venter of the ilium, which lodges the Iliacus muscle, and presents at its lower part the orifice of a nutrient canal; and below this a smooth, rounded border (iliac portion of the linea ilio-pectinea), which separates the iliac fossa from that portion of the internal surface which enters into
the formation of the true pelvis, and which gives attachment to part of the Obturator internus muscle. Behind the iliac fossa is a rough surface divided into two portions, an anterior and a posterior. The anterior auricular portion, so called from its resemblance in shape to the car, is coated with cartilage in the recent state, and articulates with a surface of similar shape on the side of the sacrum. The posterior portion is rough, for the attachment of the posterior sacro-iliac ligaments and for a part of the origin of the Erector spine.

The crest of the ilium is convex in its general outline and sinuously curved, being bent inward anteriorly, outward posteriorly. It is longer in the male than in the male, than the female, and thinner at the centre than at the extremities. It terminates at either end in a prominent eminence, the anterior superior and posterior superior spinous process. The surface of the crest is broad, and divided into an external lip, an internal lip, and an intermediate space. To the external lip is attached the Tensor vaginalis femoris, Obliquus externus abdominis, and Latissimus dorsi, and by its whole length the fascia lata; to the space between the lips, the Internal oblique; to the internal lip, the Transversalis, Quadratus lumborum, and Erector spine, the Iliacus, and the fascia iliaca.

The anterior border of the ilium is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the anterior superior spinous process of the ilium, the outer border of which gives attachment to the fascia lata and the origin of the Tensor vaginalis femoris; its inner border, to the Iliacus; whilst its extremity affords attachment to Poupart's ligament and the origin of the Sartorius. Beneath this eminence is a notch which gives attachment to the Sartorius muscle, and across which passes the external cutaneous nerve. Below the notch is the anterior inferior spinous process, which terminates in the upper lip of the acetabulum; it gives attachment to the straight tendon of the Rectus femoris muscle and the iliolumbar ligament. On the inner side of the anterior inferior spinous process is a broad, shallow groove, over which passes the Iliacus muscle. This groove is bounded internally by an eminence, the ilio-pectineal, which marks the point of union of the ilium and os pubis.

The posterior border of the ilium, shorter than the anterior, also presents two projections separated by a notch, the posterior superior and the posterior inferior spinous processes. The former corresponds with that portion of the posterior surface of the ilium which serves for the attachment of the oblique portion of the sacro-iliac ligaments and the Multifidus spine; the latter to the auricular portion which articulates with the sacrum. Below the posterior inferior spinous process is a deep notch, the great sciatic or ilio-sciatic.

The Ischium forms the lower and back part of the os innominatum. It is divisible into a thick and solid portion, the body; a large, rough eminence, on which the body rests in sitting, the tuberosity; and a thin, ascending part, the ramus.

The body, somewhat triangular in form, presents three surfaces, external, internal, and posterior; and three borders, external, internal, and posterior. The external surface corresponds to that portion of the acetabulum formed by the ischium; it is smooth and concave, and forms a little more than two-fifths of the acetabular cavity; its outer margin is bounded by a prominent rim or lip, the external border, to which the cotyloid fibro-cartilage is attached. Below the acetabulum, between it and the tuberosity, is a deep groove, along which the tendon of the Obturator externus muscle runs as it passes outward to be inserted into the digital fossa of the femur. The internal surface is smooth, concave, and enters into the formation of the lateral boundary of the true pelvic cavity. This surface is perforated by two or three large, vascular foramina, and affords attachment to part of the Obturator internus muscle. The posterior surface is quadrilateral in form, broad and smooth. Below, where it joins the tuberosity, it presents a groove continuous with that on the external surface, for the tendon of the Obturator externus muscle. The lower edge of this groove is formed by the tuberosity of the ischium, and affords attachment to the Gemellus inferior muscle. This surface is
limited, in front, by the margin of the acetabulum; behind, by the posterior border; it supports the Pyriformis, the two Gemelli, and the Obturator internus muscles in their passage outward to the great trochanter. The external border forms the prominent rim of the acetabulum, and separates the posterior from the external surface. To it is attached the cotyloid fibro-cartilage. The internal border is thin, and forms the outer circumference of the obturator foramen. The posterior border of the body of the ischium presents, a little below the centre, a thin and pointed, triangular eminence, the spine of the ischium, more or less elongated in different subjects; its external surface gives attachment to the Gemellus superior, its internal surface to the Coccygeus and Levator ani; whilst to the pointed extremity is connected the lesser sacro-sciatic ligament. Above the spine is a notch of a large size, the great sciatic, converted into a foramen by the lesser sacro-sciatic ligament; it transmits the Pyriformis muscle, the gluteal vessels and superior gluteal nerve passing out of the pelvis above the muscles; the sciatic vessels, the greater and lesser sciatic nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus below it. Below the spine is a smaller notch, the lesser sciatic; it is smooth, coated in the recent state with cartilage, the surface of which presents numerous markings corresponding to the subdivisions of the tendon of the Obturator internus, which winds over it. It is converted into a foramen by the sacro-sciatic ligaments, and transmits the tendon of the Obturator internus, the nerve which supplies that muscle, and the internal pudic vessels and nerve.

The tuberosity presents for examination three surfaces: external, internal, and inferior. The external surface is quadrilateral in shape, and rough for the attachment of muscles. It is bounded above by the groove for the tendon of the Obturator externus; in front it is limited by the posterior margin of the obturator foramen, and below it is continuous with the ramus of the bone; behind, it is bounded by a prominent margin which separates it from the inferior surface. In front of this margin the surface gives attachment to the Quadratus femoris, and anterior to this to some of the fibres of origin of the Obturator externus. The lower part of the surface gives origin to part of the Adductor magnus. The internal surface forms part of the bony wall of the true pelvis. In front it is limited by the posterior margin of the obturator foramen. Behind, it is bounded by a sharp ridge, for the attachment of a falciform prolongation of the great sacro-sciatic ligament; it presents a groove on the inner side of this for the lodgment of the internal pudic vessels and nerve; and, more anteriorly, has attached the Transversus perinei and Erector penis muscles. The inferior surface is divided into two portions—an anterior, rough, somewhat triangular part, and a posterior, smooth, quadrilateral portion. The anterior surface is subdivided by a prominent vertical ridge, passing from base to apex, into two parts; the outer one gives attachment to the Adductor magnus; the inner to the great sacro-sciatic ligament. The posterior portion is subdivided into two facets by an oblique ridge; from the upper and outer facet arises the Semimembranosus; from the lower and inner, the Biceps and Semitendinosus.

The ramus, or ascending ramus, is the thin, flattened part of the ischium which ascends from the tuberosity upward and inward, and joins the ramus of the os pubis, their point of junction being indicated in the adult by a rough line. The outer surface of the ramus is rough, for the attachment of the Obturator externus muscle, and also some fibres of the Adductor magnus; its inner surface forms part of the anterior wall of the pelvis. Its inner border is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the descending ramus of the os pubis: to the outer one is attached the deep layer of the superficial perineal fascia, and to the inner the anterior layer of the triangular ligament of the perineum. If these two ridges are traced downward, they will be found to join with each other just behind the point of origin of the Transversus perinei muscle; here the two layers of fascia are continuous behind the posterior border of the muscle. To the inter-
vining space, just in front of the point of junction of the ridges, is attached the Transversus perinei muscle, and in front of this a portion of the crus penis vel elitoridis and the Erector penis vel elitoridis muscle. Its outer border is thin and sharp, and forms part of the inner margin of the obturator foramen.

The Os Pubis forms the anterior part of the os innominatum, and, with the bone of the opposite side, forms the front boundary of the true pelvic cavity. It is divisible into a body, a horizontal ramus, and a descending ramus.

The body is somewhat quadrilateral in shape, and presents for examination two surfaces and four borders. The anterior surface is rough, directed forward, downward, and outward. To the upper and inner angle, immediately below the crest, is attached the Adductor longus; lower down, from without inward, are attached the Obturator externus, the Adductor brevis, and the upper part of the Gracilis. The posterior surface, convex from above downward, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives attachment to the Levator ani. Obturator internus, a few muscular fibres prolonged from the bladder, and the pubo-prostatic ligaments. On the outer end of the upper border, at about its junction with the horizontal ramus, there is a prominent tubercle called the spine; to it is attached the outer pillar of the external abdominal ring and Poupart's ligament. Passing outward from the spine is a prominent ridge, pubic portion of the ilio-pectineal line, which marks the brim of the true pelvis: to it is attached a portion of the conjoined tendon of the Internal oblique and Transversalis muscles. Gimbernat's ligament, and the triangular ligament of the abdomen. Internal to the spine is the upper border or crest, which extends to the inner border of the bone. It affords attachment anteriorly to the conjoined tendon of the Internal oblique and Transversalis, and posteriorly to the Rectus and Pyramidalis muscles.

The point of junction of the crest with the inner border of the bone is called the angle; to it, as well as to the symphysis, is attached the internal pillar of the external abdominal ring. The inner border, together with that of the bone of the opposite side, forms the symphysis; it is oval, covered by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage placed between it and the central fibro-cartilage. The outer border is sharp and forms part of the circumference of the obturator foramen. The lower border is united to the descending ramus.

The horizontal ramus extends from the body to the point of junction of the os pubis with the ilium, and forms the upper part of the circumference of the obturator foramen. It presents for examination a superior, inferior, and posterior surface, and an outer extremity. The superior surface presents a continuation of the pubic portion of the ilio-pectineal line, already mentioned as commencing at the spine of the bone. In front of this ridge the surface of bone is triangular in form, wider externally than internally, smooth, and affords attachment to the Pectineus muscle. The surface is bounded externally by a rough eminence, the ilio-pectineal, which serves to indicate the point of junction of the ilium and pubes, and gives attachment to the Psoas parvus when this muscle is present. The inferior surface forms the upper boundary of the obturator foramen, and presents externally a broad and deep oblique groove, for the passage of the obturator vessels and nerve; and internally a sharp margin which forms part of the circumference of the obturator foramen, and to which the obturator membrane is attached. The posterior surface forms part of the anterior boundary of the true pelvis. It is smooth, convex from above downward, and affords attachment to the upper fibres of the obturator internus. The outer extremity, the thickest part of the ramus, forms one-fifth of the cavity of the acetabulum.

The descending ramus of the os pubis is thin and flattened. It passes outward and downward, becoming narrower as it descends, and joins with the ramus of the ischium. Its anterior surface is rough, for the attachment of muscles—the Gracilis along its inner border; a portion of the Obturator externus where it enters into the formation of the foramen of that name; and between these two muscles the
Adductores brevis and magnus from within outward. The posterior surface is smooth, and gives attachment to the Obturator internus and, close to the inner margin, to the Compressor urethrae. The inner border is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downward, and are continuous with similar ridges on the ascending ramus of the ischium; to the external one is attached the deep layer of the superficial perineal fascia, and to the internal one the anterior layer of the triangular ligament of the perineum. The outer border is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The cotyloid cavity, or acetabulum, is a deep, cup-shaped, hemispherical depression, directed downward, outward, and forward; formed internally by the os pubis, above by the ilium, behind and below by the ischium, a little less than two-fifths being formed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubic bone. It is bounded by a prominent, uneven rim, which is thick and strong above, and serves for the attachment of a fibro-cartilaginous structure which contracts its orifice and deepens the surface for articulation. It presents, on its inner side, a deep notch, the cotyloid notch, which is continuous with a circular depression, the fossa acetabuli, at the bottom of the cavity: this depression is perforated by numerous apertures, lodges a mass of fat, and its margins, as well as those of the notch, serve for the attachment of the ligamentum teres. The notch is converted, in the natural state, into a foramen by a dense ligamentous band which passes across it. Through this foramen the nutrient vessels and nerves enter the joint.

The obturator or thyroid foramen is a large aperture situated between the ischium and os pubis. In the male it is large, of an oval form, its longest diameter being obliquely from above downward; in the female it is smaller and more triangular. It is bounded by a thin, uneven margin to which a strong membrane is attached; and presents at its upper and outer part a deep groove which runs from the pelvis obliquely forward, inward, and downward. This groove is converted into a foramen by the obturator membrane, and transmits the obturator vessels and nerve.

Structure.—This bone consists of much cancellous tissue, especially where it is thick, enclosed between two layers of dense, compact tissue. In the thinner parts of the bone, as at the bottom of the acetabulum and centre of the iliac fossa, it is usually semitransparent, and composed entirely of compact tissue.

Development (Fig. 209).—By eight centres: three primary—one for the ilium, one for the ischium, and one for the os pubis; and five secondary—one for the crest of the ilium, one for the anterior inferior spinous process (said to occur more frequently in the male than the female), one for the tuberosity of the ischium, one for the symphysis pubis (more frequent in the female than the male), and one for the Y-shaped piece at the bottom of the acetabulum. These various centres appear in the following order: First, in the ilium, at the lower part of the bone, immediately above the sciatic notch, at about the eighth or ninth week; secondly, in the body of the ischium, at about the third month of fetal life; thirdly, in the body of the os pubis, between the fourth and fifth months. At birth the three primary centres are quite separate, the crest, the bottom of the acetabulum, and the rami of the ischium and pubes being still cartilaginous. About the seventh or eighth year the rami of the os pubis and ischium are almost completely ossified. About the thirteenth or fourteenth year the three divisions of the bone have extended their growth into the bottom of the acetabulum, being separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. The ilium and ischium then become joined, and lastly the os pubis, through the intervention of this Y-shaped portion. At about the age of puberty ossification takes place in each of the remaining portions, and they become joined to the rest of the bone about the twenty-fifth year.

Articulations.—With its fellow of the opposite side, the sacrum, and femur.
Attachment of Muscles.—To the ilium, sixteen. To the outer lip of the crest, the Tensor vaginae femoris, Obliquus externus abdominis, and Latissimus dorsi; to the internal lip, the Iliacus, Transversalis, Quadratus lumborum, and Erector spine; to the interspace between the lips, the Obliquus internus. To the outer surface of the ilium, the Gluteus maximus, Gluteus medius, Gluteus minimus, reflected tendon of the Rectus; to the upper part of the great sacro-sciatic notch, a portion of the Pyriformis; to the internal surface, the Iliacus; to that portion of the internal surface below the linea ilipectinea, the Obturator internus, and the Multifidus spine to the internal surface of the posterior superior spine; to the anterior border, the Sartorius and straight tendon of the Rectus. To the ischium, fourteen. To the outer surface of the ramus, the Obturator externus and Adductor magnus; to the internal surface, the Obturator internus and Erector penis. To the spine, the Gemellus superior, Levator ani, and Coccygeus. To the tuberosity, the Biceps, Semitendinosus, Semimembranosus, Quadratus femoris, Adductor magnus.

By eight centres { Three primary (Ilium, Ischium, and Os Pubis).
 Five Secondary.

Gemellus inferior, Transversus perinei, Erector penis. To the os pubis, sixteen: Obliquus externus, Obliquus internus, Transversalis, Rectus, Pyramidalis, Psoas parvus, Pectineus, Adductor magnus, Adductor longus, Adductor brevis, Gracilis, Obturator externus and internus, Levator ani, Compressor urethrae, and occasionally a few fibres of the Accelerator urinæ.

The Pelvis (Figs. 210, 211).

The Pelvis, so called from its resemblance to a basin (L. pelvis), is stronger and more massively constructed than either the cranial or thoracic cavity; it is a bony ring, interposed between the lower end of the spine, which it supports, and the lower extremities, upon which it rests. It is composed of four bones: the two ossa innominati, which bound it on either side and in front, and the sacrum and coccyx, which complete it behind.

The pelvis is divided by a plane passing through the prominence of the sacrum,
the linea ilio-pectinea, and the upper margin of the symphysis pubis into the false and true pelvis.

The false pelvis is all that expanded portion of the pelvic cavity which is situated above this plane. It is bounded on each side by the ossa ilii; in front it is incomplete, presenting a wide interval between the spinous processes of the ilia on either side, which is filled up in the recent state by the parietes of the abdomen; behind, in the middle line, is a deep notch. This broad, shallow cavity is fitted to support the intestines and to transmit part of their weight to the anterior wall of the abdomen, and is, in fact, really a portion of the abdominal cavity. The term false pelvis is incorrect, and this space ought more properly to be regarded as part of the hypogastric region of the abdomen.

The true pelvis is all that part of the pelvic cavity which is situated beneath
the plane. It is smaller than the false pelvis, but its walls are more perfect. For convenience of description it is divided into a superior circumference or inlet, an inferior circumference or outlet, and a cavity. The superior circumference forms the margin or brim of the pelvis, the included space being called the inlet. It is formed by the linea ilio-pectinea, completed in front by the crests of the pubic bones, and behind by the anterior margin of the base of the sacrum and sacro-vertebral angle. The inlet of the pelvis is somewhat heart-shaped obtusely pointed in front, diverging on either side, and encroached upon behind by the projection forward of the promontory of the sacrum. It has three principal diameters: antero-posterior (sacro-pubic), transverse, and oblique. The antero-posterior extends from the sacro-vertebral angle to the symphysis pubis; its average measurement is four inches in the male, four and three-quarters in the female. The transverse extends across the greatest width of the inlet, from the middle of the brim on one side to the same point on the opposite; its average measurement is four and a half in the male, five and a quarter in the female. The oblique extends from the margin of the pelvis, corresponding to the ilio-pectineal eminence on one side, to the sacro-iliac symphysis on the opposite side; its average measurement is four and a quarter in the male, and five in the female.

The cavity of the true pelvis is bounded in front by the symphysis pubis; behind, by the concavity of the sacrum and coccyx, which, curving forward above and below, contracts the inlet and outlet of the canal; and laterally it is bounded by a broad, smooth, quadrangular surface of bone, corresponding to the inner surface of the body of the ischium and that part of the ilium which is below the ilio-pectineal line. The cavity is shallow in front, measuring at the symphysis an inch and a half in depth, three inches and a half in the middle, and four inches and a half posteriorly. From this description it will be seen that the cavity of the pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall, and broader in the middle than at either extremity, from the projection forward of the sacro-coccygeal column above and below. This cavity contains, in the recent subject, the rectum, bladder, and part of the organs of generation. The rectum is placed at the back of the pelvis, and corresponds to the curve of the sacro-coccygeal column; the bladder in front, behind the symphysis pubis. In the female the uterus and vagina occupy the interval between these parts.

The lower circumference of the pelvis is very irregular, and forms what is called the outlet. It is bounded by three prominent eminences: one posterior, formed by the point of the coccyx; and one on each side, the tuberosities of the ischia. These eminences are separated by three notches; one in front, the pubic arch, formed by the convergence of the rami of the ischia and pubic bones on each side. The other notches, one on each side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above; they are called the sacro-sciatic notches; in the natural state they are converted into foramina by the lesser and greater sacro-sciatic ligaments. In the recent state, when the ligaments are in situ, the outlet of the pelvis is lozenge-shaped, bounded in front by the subpubic ligament and the rami of the os pubis and ischium; on each side by the tuberosities of the ischia; and behind by the great sacro-sciatic ligaments and the tip of the coccyx.

The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The antero-posterior extends from the tip of the coccyx to the lower part of the symphysis pubis; its average measurement is three and a quarter inches in the male and five in the female. The antero-posterior diameter varies with the length of the coccyx, and is capable of increase or diminution on account of the mobility of that bone.\(^1\) The transverse extends from the posterior part of one

\(^1\) The measurements of the pelvis given above are, I believe, fairly accurate, but different measurements are given by various authors, no doubt due in a great measure to differences in the physique and stature of the population from whom the measurements have been taken. The accompany-
ischiatic tuberosity to the same point on the opposite side: the average measurement is three and a half inches in the male and four and three-quarters in the female.

**Position of the Pelvis.**—In the erect posture the pelvis is placed obliquely with regard to the trunk of the body: the bony ring, which separates the true from the false pelvis, and which forms the essential part of the pelvis, is placed so as to form an angle of about 60° to 65° with the ground on which we stand. The pelvic surface of the symphysis pubis looks upward and backward, the concavity of the sacrum and coccyx downward and forward, the base of the sacrum in well-formed female bodies being nearly four inches above the upper border of the symphysis pubis, and the apex of the coccyx a little more than half an inch above its lower border. The obliquity is much greater in the fetus and at an early period of life than in the adult. In consequence of this obliquity of the pelvis the line of gravity of the head, which passes through the middle of the odontoid process of the axis and through the points of junction of the curves of the vertebral column to the sacro-vertebral angle, descends toward the front of the cavity, so that it bisects a line drawn transversely through the middle of the heads of the thigh-bones. And thus the centre of gravity of the head is placed immediately over the heads of the thigh-bones on which the trunk is supported.

**Axes of the Pelvis (Fig. 212).**—The plane of the inlet of the true pelvis will be represented by a line drawn from the base of the sacrum to the upper margin of the symphysis pubis. A line carried at right angles with this at its middle would correspond at one extremity with the umbilicus, and at the other with the middle of the coccyx: the axis of the inlet is therefore directed downward and backward. The axis of the outlet, produced upward, would touch the base of the sacrum, and is therefore directed downward and forward. The axis of the cavity is curved like the cavity itself: this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the inlet and outlet. A knowledge of the direction of these axes serves to explain the course of the fœtus in its passage through the pelvis during parturition. It is also important to the surgeon, as indicating the direction of the force required in the removal of calculi from the bladder, and as determining the direction in which instruments should be used in operations upon the pelvic viscera.

**Differences between the Male and Female Pelvis.**—The female pelvis, looked at as a whole, is distinguished from the male by the bones being more delicate, by its width being greater and its depth smaller. The whole pelvis is less massive, and its bones are lighter and more slender, and its muscular impressions are slightly marked. The iliac fossae are broad and expanded, and the anterior iliac spines widely separated; hence the greater prominence of the hips. The inlet in the female is larger than in the male; it is more nearly circular, and the sacro-vertebral angle projects less forward. The cavity is shallower and wider; the sacrum is shorter and wider, and its lower half forms a greater angle with its upper; the obturator foramina are triangular, and smaller in size than in the male. The outlet is larger and the coccyx more movable. The spines of the ischia project less in-

---

THE PELVIS. 283

ward. The tuberosities of the ischia and the acetabula are wider apart. The pubic arch is wider and more rounded than in the male, where it is an angle rather than an arch; its pillars are somewhat excavated, and sloped from within outward, so that their inner surfaces look forward. In consequence of this the width of the fore part of the pelvic outlet is much increased and the passage of the fetal head facilitated.  

The size of the pelvis varies, not only in the two sexes, but also in different members of the same sex. This does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelvies. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure an inch less than the average, and this even in women of average height and otherwise well formed. The principal divergences, however, are found at the inlet, and affect the relation of the antero-posterior to the transverse diameter. Thus we may have a pelvis the inlet of which is elliptical either in a transverse or antero-posterior direction; the transverse diameter in the former and the antero-posterior in the latter greatly exceeding the other diameters. Again, the inlet of the pelvis in some instances is seen to be almost circular. 

The same differences are found in various races. European women are said to have the most roomy pelvies. That of the negress is smaller, circular in shape, and with a narrow pubic arch. The Hottentots and Bushwomen possess the smallest pelvies.

In the fetus and for several years after birth the pelvis is small in proportion to that of the adult. The cavity is deep, and the projection of the sacro-vertebral angle less marked. The antero-posterior and transverse diameters are nearly equal. About puberty the pelvis in both sexes presents the general characters of the adult male pelvis; but after puberty it acquires its proper sexual characters.

**Surface Form.**—The pelvic bones are so thickly covered with muscles that it is only at certain points that they approach the surface and can be felt through the skin. In front, the anterior superior spinous process is easily to be recognized; a portion of it is subcutaneous, and in thin subjects may be seen to stand out as a prominence at the outer extremity of the line of the groin. In fat subjects its position is marked by an oblique depression amongst the surrounding fat, at the bottom of which the bony process may be felt. Proceeding upward and outward from this process, the crest of the ilium may be traced throughout its whole length, sinusously curved. It is represented, in muscular subjects, on the surface, by a groove or furrow, the iliac furrow, caused by the projection of fleshy fibres of the External oblique muscle of the abdomen. It terminates behind in the posterior superior spinous process, the position of which is indicated by a slight depression on a level with and on each side of the spinous process of the second sacral vertebra. Between the two posterior superior spinous processes, but at a lower level, is to be felt the spinous process of the third sacral vertebra (see page 164). Another part of the bony pelvis which is easily accessible to the touch is the tuberosity of the ischium, situated beneath the gluteal fold, and, when the hip is flexed, easily to be felt, as it is then to a great extent uncovered by muscle. Finally, the spine of the os pubis can always be readily felt, and constitutes an important surgical guide, especially in connection with the subject of hernia. It is nearly in the same horizontal line with the upper edge of the true trochanter. In thin subjects it is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by following up the tendon of origin of the Adductor longus muscle.

**Surgical Anatomy.**—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle being deficient, the bodies of the pubic bones imperfectly developed, and the symphysis absent. The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forward, and the obturator foramen diminished in size, narrowed, and turned outward. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the ilio-sacral facets turned more outward than normal, while the vertical curve is straightened.  

Fractures of the pelvis are divided into fractures of the false pelvis and of the true pelvis. Fractures of the false pelvis vary in extent: a small portion of the crest may be broken or one of the spinous processes may be torn off, and this may be the result of muscular action; or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the true pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the true pelvis. Fractures of the true pelvis generally occur through the horizontal rami of the os pubis and the ascending ramus of the ischium, as this is the weakest part of the bony ring, and may be caused either by crushing violence applied

in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together, and the bone gives way in the same place from indirect violence. Occasionally the fracture may be double, occurring on both sides of the body. It is in these cases that injury to the contained viscera is liable to take place: the urethra, the bladder, the rectum, the vagina in the female, the small intestines, and even the uterus, have all been lacerated by a displaced fragment. Fractures of the acetabulum are occasionally met with: either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity, and the head of the femur driven inward and project into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, separating the bone into its three anatomical portions.

The sacrum is occasionally, but rarely, broken by direct violence—i. e. blows, kicks, or falls on the part. The lesion may be complicated with injury to the nerves of the sacral plexus, leading to paralysis and loss of sensation in the lower extremity, or to incontinence of fæces from paralysis of the sphincter ani.

The pelvic bones often undergo important deformity in rickets, the effect of which in the adult woman may interfere seriously with childbearing. In consequence of the yielding nature of the bones, the acetabula become approximated, the symphyses is pushed forward, and the antero-posterior diameter lessened. In osteo-malacia also great deformity may occur, the pelvis becoming beak-shaped. The promontory of the sacrum is pushed forward by the weight of the body, and the sides of the pelvis are approximated by the pressure of the two thigh-bones: this gives to the pelvis the peculiar deformity which is characteristic of this disease.

THE THIGH.

The Femur, or Thigh-Bone.

The Femur (femur, the thigh) is the longest,1 largest, and strongest bone in the skeleton, and almost perfectly cylindrical in the greater part of its extent. In the erect posture it is not vertical, being separated from its fellow above by a considerable interval, which corresponds to the entire breadth of the pelvis, but inclining gradually downward and inward, so as to approach its fellow toward its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than the male, on account of the greater breadth of the pelvis. The femur, like other long bones, is divisible into a shaft and two extremities.

The Upper Extremity presents for examination a head, a neck, and the great and lesser trochanters.

The head, which is globular, and forms rather more than a hemisphere, is directed upward, inward, and a little forward, the greater part of its convexity being above and in front. Its surface is smooth, coated with cartilage in the recent state, except at a little behind and below its centre, where is an ovoid depression, for the attachment of the ligamentum teres. The neck is a flattened pyramidal process of bone which connects the head with the shaft. It varies in length and obliquity at various periods of life and under different circumstances. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the axis of the shaft. In the adult it forms an angle of about 130° with the shaft, but varies in inverse proportion to the development of the pelvis and the stature. In consequence of the prominence of the hips and widening of the pelvis in the female, the neck of the thigh-bone forms more nearly a right angle with the shaft than it does in man. It has been stated that the angle diminishes in old age and the direction of the neck becomes horizontal, but this statement is founded on insufficient evidence. Sir George Humphry states that the angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change, even in old age. He further states that the angle varies considerably in different persons of the same age. It is smaller in short than in long bones, and when the pelvis is wide.² The neck is flattened from before backward, contracted in the middle, and broader at its outer extremity, where it is connected with the shaft, than at its summit, where it is attached to the head. The vertical diameter of the outer

---

1 In a man six feet high it measures eighteen inches—one-fourth of the whole body.
² Journal of Anatomy and Physiology.
half is increased by the thickening of the lower edge, which slopes downward to join the shaft at the lesser trochanter, so that the outer half of the neck is flattened from before backward, and its vertical diameter measures one-third more than the antero-posterior. The inner half is smaller and of a more circular shape. The anterior surface of the neck is perforated by numerous vascular foramina. The posterior surface is smooth, and is broader and more concave than the anterior; it gives attachment to the posterior part of the capsular ligament of the hip-joint, about half an inch above the posterior intertrochanteric line. The superior border is short and thick, and terminates externally at the great trochanter; its surface is perforated by large foramina. The inferior border, long and narrow, curves a little backward, to terminate at the lesser trochanter.

The Trochanters (τροχαντῆς, to run or roll) are prominent processes of bone which afford leverage to the muscles which rotate the thigh on its axis. They are two in number, the great and the lesser.

The Great Trochanter is a large, irregular, quadrilaterial eminence, situated at the outer side of the neck, at its junction with the upper part of the shaft. It is directed a little outward and backward, and in the adult is about three-quarters of an inch lower than the head. It presents for examination two surfaces and four borders. The external surface, quadrilateral in form, is broad, rough, convex, and marked by a prominent diagonal line, which extends from the posterior superior to the anterior inferior angle; this line serves for the attachment of the tendon of the Gluteus medius. Above the line is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between that tendon and the bone. Below and behind the diagonal line is a smooth, triangular surface, over which the tendon of the Gluteus maximus muscle plays, a bursa being interposed. The internal surface is of much less extent than the external, and presents at its base a deep depression, the digital or trochanteric fossa, for the attachment of the tendon of the Obturator externus muscle, and in front of this an impression for the attachment of the Obturator internus and Gemelli. The superior border is free; it is thick and irregular, and marked near the centre by an impression for the attachment of the Pyriformis. The inferior border corresponds to the point of junction of
the base of the trochanter with the outer surface of the shaft; it is marked by a rough, prominent, slightly curved ridge, which gives attachment to the upper part of the Vastus externus muscle. The anterior border is prominent, somewhat irregular, as well as the surface of bone immediately below it; it affords attachment at its outer part to the Gluteus minimus. The posterior border is very prominent, and appears as a free, rounded edge, which forms the back part of the digital fossa.

The Lesser Trochanter is a conical eminence which varies in size in different subjects; it projects from the lower and back part of the base of the neck. Its base is triangular, and connected with the adjacent parts of the bone by three well-marked borders: two of these are above—the internal continuous with the lower border of the neck, the external with the posterior intertrochanteric line—while the inferior border is continuous with the middle division of the linea aspera. Its summit, which is directed inward and backward, is rough, and gives insertion to the tendon of the Psoas magnus. The Iliacus is inserted into the shaft below the lesser trochanter between the Vastus internus in front and the Pectineus behind.

A well-marked prominence of variable size, which projects from the upper and front part of the neck at its junction with the great trochanter, is called the tubercle of the femur; it is the point of meeting of the Gluteus minimus externally and above, and the Vastus externus below. Running obliquely downward and inward from the tubercle is the spiral line of the femur, or anterior intertrochanteric line; it winds round the inner side of the shaft, below the lesser trochanter, and terminates in the linea aspera, about two inches below this eminence. Its upper half is rough, and affords attachment to the capsular ligament of the hip-joint; its lower half is less prominent, and gives attachment to the upper part of the Vastus internus. Running obliquely downward and inward from the summit of the great trochanter on the posterior surface of the neck is a very prominent, well-marked ridge, the posterior intertrochanteric line. Its upper half forms the posterior border of the great trochanter, and its lower half runs downward and inward across the neck of the bone to the upper and back part of the lesser trochanter. A slight ridge sometimes commences about the middle of the posterior intertrochanteric line, and passes vertically downward for about two inches along the back part of the shaft: it is called the linea quadrati, and gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus muscles.¹

The Shaft, almost cylindrical in form, is a little broader above than in the centre, and somewhat flattened below, from before backward. It is slightly arched, so as to be convex in front and concave behind, where it is strengthened by a prominent longitudinal ridge, the linea aspera. It presents for examination three borders, separating three surfaces. Of the three borders, one, the linea aspera, is posterior; the other two are placed laterally.

The linea aspera (Fig. 214) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting an external lip, an internal lip, and a rough intermediate space. Above, this crest is prolonged by three ridges. The most external one is very rough, and is continued almost vertically upward to the base of the great trochanter. It is sometimes termed the gluteal ridge, and gives attachment to part of the Gluteus maximus muscle; its upper part is often elongated into a roughened crest, on which is a more or less well-marked, rounded tubercle, a rudimental third trochanter. The middle ridge, the least distinct, is continued to the base of the trochanter minor, and the internal one is lost above in the spiral line of the femur. Below, the linea aspera is prolonged by two ridges, which enclose between them a triangular space, the popliteal surface. Of these two ridges, the outer one is the more prominent, and descends to the summit of the outer condyle (external

¹Generally there is merely a slight thickening about the centre of the intertrochanteric line, marking the point of attachment of the Quadratus femoris. This is termed by some anatomists the tubercle of the Quadratus.
supracondylar line). The inner one (internal supracondylar line) is less marked, especially at its upper part, where it is crossed by the femoral artery. It terminates, below, at the summit of the internal condyle, in a small tubercle, the Adductor tubercle, which affords attachment to the tendon of the Adductor magnus.

To the inner lip of the linea aspera and its inner prolongation above and below is attached the Vastus internus, and to the outer lip and its outer prolongation above is attached the Vastus externus. The Adductor magnus is attached to the linea aspera, to its outer prolongation above and its inner prolongation below. Between the Vastus externus and the Adductor magnus are attached two muscles—viz. the Gluteus maximus above, and the short head of the Biceps below. Between the Adductor magnus and the Vastus internus four muscles are attached: the Iliacus and Pectineus above (the latter to the middle of the upper divisions); below these, the Adductor brevis and Adductor longus. The linea aspera is perforated a little below its centre by the nutrient canal, which is directed obliquely upward.

The two lateral borders of the femur are only slightly marked, the outer one extending from the anterior inferior angle of the great trochanter to the anterior extremity of the external condyle; the inner one from the spiral line, at a point opposite the trochanter minor, to the anterior extremity of the internal condyle. The internal border marks the limit of attachment of the Crureus muscle internally.

The anterior surface includes that portion of the shaft which is situated between the two lateral borders. It is smooth, convex, broader above and below than in the centre, slightly twisted, so that its upper part is
directed forward and a little outward, its lower part forward, and a little inward. To the upper three-fourths of this surface the Crureus is attached; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa, and affords attachment to the Subcrureus to a small extent. The external surface includes the portion of bone between the external border and the outer lip of the linea aspera: it is continuous above with the outer surface of the great trochanter, below with the outer surface of the external condyle; to its upper three-fourths is attached the outer portion of the Crureus muscle. The internal surface includes the portion of bone between the internal border and the inner lip of the linea aspera; it is continuous above with the lower border of the neck, below with the inner side of the internal condyle; it is covered by the Vastus internus muscle.

The Lower Extremity, larger than the upper, is of a cuboid form, flattened from before backward, and divided into two large eminences, the condyles (κόνδυλος, a knuckle), by an interval which presents a smooth depression in front called the trochlea, and a notch of considerable size behind—the intercondylar notch. The external condyle is the more prominent anteriorly, and is the broader both in the antero-posterior and transverse diameters. The internal condyle is the narrower, longer, and more prominent inferiorly. This difference in the length of the two condyles is only observed when the bone is perpendicular, and depends upon the obliquity of the thigh-bones, in consequence of their separation above at the articulation with the pelvis. If the femur is held obliquely, the surfaces of the two condyles will be seen to be nearly horizontal. The two condyles are directly continuous in front, and form a smooth trochlear surface, which articulates with the patella. It presents a median groove, which extends downward and backward to the intercondylar notch; and two lateral convexities, of which the external is the broader, more prominent, and prolonged farther upward upon the front of the outer condyle. The external border is also more prominent, and ascends higher than the internal one. The intercondylar notch lodges the crucial ligaments; it is bounded laterally by the opposed surfaces of the two condyles, and in front by the lower end of the shaft.

Outer Condyle.—The outer surface of the external condyle presents, a little behind its centre, an eminence, the outer tuberosity; it is less prominent than the inner tuberosity, and gives attachment to the external lateral ligaments of the knee. Immediately beneath it is a groove which commences at a depression a little behind the centre of the lower border of this surface: the front part of this depression gives origin to the Popliteus muscle, the tendon of which is lodged in the groove during flexion of the knee. The groove is smooth, lined with synovial membrane in the recent state, and runs to the posterior extremity of the condyle. The inner surface of the outer condyle forms one of the lateral boundaries of the intercondylar notch, and gives attachment, by its posterior part, to the anterior crucial ligament. The inferior surface is convex, smooth, and broader than that of the internal condyle. The posterior extremity is convex and smooth; just above the articular surface is a depression for the tendon of the outer head of the Gastrocnemius, above which is the origin of the Plantaris.

Inner Condyle.—The inner surface of the inner condyle presents a convex eminence, the inner tuberosity, rough for the attachment of the internal lateral ligament. The outer side of the inner condyle forms one of the lateral boundaries of the intercondylar notch, and gives attachment, somewhat posteriorly, to the posterior crucial ligament. Its inferior or articular surface is convex, and presents a less extensive surface than the external condyle. Just above the articular surface of the condyle, behind, is a depression for the tendon of origin of the inner head of the Gastrocnemius.

Structure.—The shaft of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The cylinder is of great thickness and density in the middle third of the shaft, where the bone is narrowest and the medullary canal well formed; but above and below this the cylinder gradually becomes thinner,
owing to a separation of the layers of the bone into cancelli, which project into the medullary canal and finally obliterate it, so that the upper and lower ends of the shaft, and the articular extremities more especially, consist of cancellated tissue invested by a thin, compact layer.

The arrangement of the cancelli in the ends of the femur is remarkable. In the upper end they are arranged in two sets. One, starting from the top of the head, the upper surface of the neck, and the great trochanter, converge to the inner circumference of the shaft (Fig. 215); these are placed in the direction of greatest pressure, and serve to support the vertical weight of the body. The second set are planes of lamellae intersecting the former nearly at right angles, and are situated in the line of the greatest tension—that is to say, along the lines in which the muscles and ligaments exert their traction. In the head of the bone these planes are arranged in a curved form, in order to strengthen the bone when exposed to pressure in all directions. In the midst of the cancellous tissue of the neck is a vertical plane of compact bone, the femoral spur (calcar femorale) which commences at the point where the neck joins the shaft midway between the lesser trochanter and the internal border of the shaft of the bone, and extends in the direction of the digital fossa (Fig. 216). This materially strengthens this portion of the bone. Another point in connection with the structure of the neck of the femur requires mention, especially on account of its influence on the production of fracture in this situation. It will be noticed that a considerable portion of the great trochanter lies behind the level of the posterior surface of the neck; and if a section be made through the trochanter at this level, it will be seen that the posterior wall of the neck is prolonged into the trochanter. This prolongation is termed by Bigelow the "true neck," and forms a thin, dense plate of bone, which passes beneath the posterior intertrochanteric ridge toward the outer surface of the bone.

In the lower end the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, however, horizontal planes of cancellous tissue

---

1 Bigelow on the Hip, p. 121.
are to be seen, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of rectangular areas.

**Articulations.**—With three bones: the os innominatum, tibia, and patella.

**Development (Fig. 217).**—The femur is developed by five centres: one for the shaft, one for each extremity, and one for each trochanter. Of all the long bones, except the clavicle, it is the first to show traces of ossification; this commences in the shaft, at about the fifth week of foetal life, the centres of ossification in the epiphyses appearing in the following order: First, in the lower end of the bone, at the ninth month of foetal life¹ (from this the condyles and tuberosities are formed); in the head at the end of the first year after birth; in the greater trochanter, during the fourth year; and in the lesser trochanter, between the thirteenth and fourteenth. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance: their junction does not commence until after puberty, the lesser trochanter being first joined, then the great, then the head, and, lastly, the inferior extremity (the first in which ossification commenced), which is not united until the twentieth year.

**Attachment of Muscles.**—To twenty-three. To the great trochanter: the Gluteus medius, Gluteus minimus, Pyriformis, Obturator internus, Obturator externus, Gemellus superior, Gemellus inferior, and Quadratus femoris. To the lesser trochanter: the Psoas magnus and the Iliacus below it. To the shaft: the Vastus externus, Gluteus maximus, short head of the Biceps, Vastus internus, Adductor magnus, Pectineus, Adductor brevis, Adductor longus, Crureus, and Subcurreus. To the condyles: the Gastrocnemius, Plantaris, and Popliteus.

**Surface Form.**—The femur is covered with muscles, so that in fairly muscular subjects the shaft is not to be detected through its fleshy covering, and the only parts accessible to the touch are the outer surface of the great trochanter and the lower expanded end of the bone. The external surface of the great trochanter is to be felt, especially in certain positions of the limb. Its position is generally indicated by a depression, owing to the thickness of the Gluteus medius and minimus, which project above it. When, however, the thigh is flexed, and especially if crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The upper border is about on a line with the spine of the os pubis, and its exact position is indicated by a line drawn from the anterior superior spinous process of the ilium, over the outer side of the hip, to the most prominent point of the tuberosity of the ischiium. This is known as Nélaton's line. The outer and inner condyles of the lower extremity are easily to be felt. The outer one is more subcutaneous than the inner one, and readily felt. The tuberosity on it is comparatively little developed, but can be more or less easily recognized. The inner condyle is more thickly covered, and this gives a general convex outline to this part, especially when the knee is flexed. The tuberosity on it is easily felt, and at the upper part of the condyle the sharp tuberele for the insertion of the tendon of the Adductor magnus can be recognized without difficulty. When the knee is flexed, and the patella situated in the interval between the condyles and the upper end of the tibia, a part of the trocharce surface of the femur can be made out above the patella.

**Surgical Anatomy.**—There are one or two points about the ossification of the femur

¹ This is the only epiphysis in which ossification begins before birth.
THE PATELLA.

bearing on practice to which allusion must be made. It has been stated above that the lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of this ossific centre is, therefore, a proof, in newly-born children found dead, that the child has arrived at the full period of utero-gestation, and is always relied upon in medico-legal investigations. The position of the epiphysial line should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the knee, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphysial cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render it almost useless. Separation of the lower epiphysis may take place up to the age of twenty, at which time it becomes completely joined to the shaft of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The upper epiphysis of the femur is of interest principally on account of its being the seat of origin of a large number of cases of tubercular disease of the hip-joint. The disease commences in the majority of cases in the highly vascular and growing tissue in the neighborhood of the epiphysis, and from here extends into the joint.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the shaft; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the great trochanter; (3) fracture of the great trochanter; and (4) separation of the epiphysis, either of the head or of the great trochanter. The first of these, fracture of the neck, is usually termed intracapsular fracture, but this is scarcely a correct designation, as, owing to the attachment of the capsular ligament, the fracture may be partly within and partly without the capsule, when the fracture occurs at the lower part of the neck. It generally occurs in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of the fracture taking place in old people is in consequence of the degenerative changes which the bone has undergone. Morkel believes that it is mainly due to the absorption of the calcare femorale. These fractures are occasionally impacted. As a rule they unite by fibrous tissue, and frequently no union takes place, and the surfaces of the fracture become smooth and eburnated.

Fractures of the neck of the shaft with the great trochanter are usually termed extracapsular, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the anterior intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the great trochanter, as from a blow or fall laterally on the hip. From the manner in which the accident is caused, the neck of the bone is driven into the trochanter, where it may remain impacted, or the trochanter may be split up into two or more fragments, and thus no fixation takes place.

Fractures of the great trochanter may be either "oblige fracture through the trochanter major, without implicating the neck of the bone" (Astley Cooper), or separation of the great trochanter. Most of the recorded cases of this latter injury occurred in young persons, and were probably cases of separation of the epiphysis of the great trochanter. Separation of the epiphysis of the head of the femur has been said to occur, but, as far as I know, has never been verified by post-mortem examination.

Fractures of the shaft may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence or by muscular action. Fractures of the upper third of the shaft are almost always the result of indirect violence, whilst those of the lower third are the result, for the most part, of direct violence. In the middle third fractures occur from both forms of injury in about equal proportions. Fractures of the shaft are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture, separating either the internal or external condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur as well as the other bones of the leg are frequently the seat of acute necrosis in young children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Tumors not infrequently are found growing from the femur: the most common forms being sarcoma, which may grow either from the periosteum or from the medullary tissue within the interior of the bone; and exostosis, which is commonly found originating in the neighborhood of the epiphysial cartilage of the lower end.

THE LEG.

The skeleton of the Leg consists of three bones: the Patella, a large sesamoid bone, placed in front of the knee; the Tibia; and the Fibula.

The Patella (Figs. 218, 219).—The Patella (patella, a small pan) is a flat, triangular bone, situated at the
anterior part of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps extensor. It resembles these bones 
(1) in its being developed in a tendon; (2) in its centre of ossification presenting a knotty or tuberelalated outline similar to other sesamoid bones; (3) in its structure being composed mainly of dense cancellous tissue, as in the other sesamoid bones. It serves to protect the front of the joint, and increases the leverage of the Quadriceps extensor by making it act at a greater angle. It presents an
anterior and posterior surface, three borders, and an apex.
The anterior surface is convex, perforated by small apertures, for the passage of nutrient vessels, and marked by numerous rough, longitudinal striae. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps extensor, which is continuous below with the superficial fibres of the ligamentum patellae. It is separated from the integument by a bursa. The posterior surface presents a smooth, oval-shaped, articular surface, covered with cartilage in the recent state, and divided into two facets by a vertical ridge, which descends from the superior border toward the inferior angle of the bone. The ridge corresponds to the groove on the trochlear surface of the femur, and the two facets to the articular surfaces of the two condyles; the outer facet, for articulation with the outer condyle, being the broader and deeper. This character serves to indicate the side to which the bone belongs. Below the articular surface is a rough, convex, non-articular depression, the lower half of which gives attachment to the ligamentum patellae, the upper half being separated from the head of the tibia by adipose tissue, in which may be found a bursa.
The superior border is thick, and sloped from behind, downward and forward: it gives attachment to that portion of the Quadriceps extensor which is derived from the Rectus and Crureus muscles. The lateral borders are thinner, converging below. They give attachment to that portion of the Quadriceps extensor derived from the external and internal Vasti muscles. 
The apex is pointed, and gives attachment to the ligamentum patellae.
Structure.—It consists of a nearly uniform dense cancellous tissue covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the posterior articular surface toward the other parts of the bone.
Development.—By a single centre, which makes its appearance, according to Béclard, about the third year. In two instances I have seen this bone cartilaginous throughout, at a much later period (six years). More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.
Articulations.—With the two condyles of the femur.
Attachment of Muscles.—To four: the Rectus, Crureus, Vastus internus, and Vastus externus. These muscles, joined at their insertion, constitute the Quadriceps extensor cruris.
Surface Form.—The external surface of the patella can be seen and felt in front of the knee. In the extended position of the limb the internal border is a little more prominent than the outer, and if the Quadriceps extensor is relaxed, the bone can be moved from side to side and appears to be loosely fixed. If the joint is flexed, the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly fixed against the femur.
Surgical Anatomy.—The main surgical interest about the patella is in connection with fractures; which are of common occurrence. They may be produced by muscular action; that
is to say, by violent contraction of the Quadriceps extensor while the limb is in a position of semi-flexion, so that the bone is snapped across the condyles; or by direct violence, such as falls on the knee. In the former class of cases the fracture is transverse; in the latter it may be oblique, longitudinal, stellate, or the bone variously comminuted. The principal interest in these cases attaches to their treatment. Owing to the wide separation of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue, and this may subsequently stretch, producing wide separation of the fragments and permanent lameness. Various plans, including opening the joint and suturing the fragments, have been advocated for overcoming this difficulty.

In the larger number of cases of fracture of the patella the knee-joint is involved, the cartilage which covers its posterior surface being also torn. In some cases of fracture from direct violence, however, this need not necessarily happen, the lesion involving only the superficial part of the bone; and, as Morris has pointed out, it is an anatomical possibility, in complete fracture, if the lesion involve only the lower and non-articular part of the bone, for it to take place without injury to the synovial membrane.

The Tibia (Figs. 220, 221).

The Tibia (tibia, a flute or pipe) is situated at the front and inner side of the leg, and, excepting the femur, is the longest and largest bone in the skeleton. It is prismatic in form, expanded above, where it enters into the knee-joint, more slightly enlarged below. In the male its direction is vertical and parallel with the bone of the opposite side; but in the female it has a slightly oblique direction downward and outward, to compensate for the oblique direction of the femur inward. It presents for examination a shaft and two extremities.

The Upper Extremity, or Head, is large, and expanded on each side into two lateral eminences, the tuberosities. Superiorly, the tuberosities present two smooth, concave surfaces, which articulate with the condyles of the femur; the internal, articular surface is longer, deeper, and narrower than the external, oval from before backward, to articulate with the internal condyle; the external one is broader, flatter, and more circular, to articulate with the external condyle. Between the two articular surfaces, and nearer the posterior than the anterior aspect of the bone, is an eminence, the spinous process of the tibia, surmounted by a prominent tubercle on each side, which gives attachment to the extremities of the semilunar fibro-cartilages; in front and behind the spinous process is a rough depression for the attachment of the anterior and posterior crucial ligaments and the semilunar fibro-cartilages. The anterior surfaces of the tuberosities are continuous with one another, forming a single large surface, which is somewhat flattened: it is triangular, broad above, and perforated by large vascular foramina; narrow below, where it terminates in a prominent oblong elevation of large size, the tubercle of the tibia; the lower half of this tubercle is rough, for the attachment of the ligamentum patellae; the upper half presents a smooth facet supporting, in the recent state, a bursa which separates the ligament from the bone. Posteriorly the tuberosities are separated from each other by a shallow depression, the popliteal notch, which gives attachment to part of the posterior crucial ligament and part of the posterior ligament of the knee-joint. The inner tuberosity presents posteriorly a deep transverse groove, for the insertion of one of the fasciculi of the tendon of the Semi-membranosus. Its lateral surface is convex, rough, and prominent: it gives attachment to the internal lateral ligament. The outer tuberosity presents posteriorly a flat articular facet, nearly circular in form, directed downward, backward, and outward, for articulation with the fibula. Its lateral surface is convex and rough, more prominent in front than the internal: it presents a prominent rough eminence, situated on a level with the upper border of the tubercle of the tibia, for the attachment of the ilio-tibial band. Just below this the Extensor longus digitorum and a slip from the Biceps are attached.

The Shaft of the tibia is of a triangular prismatic form, broad above, gradually decreasing in size to its most slender part, at the commencement of its lower fourth, where fracture most frequently occurs; it then enlarges again toward its lower extremity. It presents for examination three borders and three surfaces.

The anterior border, the most prominent of the three, is called the crest of the
The tibia, or, in popular language, the shin; it commences above at the tuberele, and terminates below at the anterior margin of the inner malleolus. This border is very prominent in the upper two-thirds of its extent, smooth and rounded below. It presents a very flexuous course, being usually curved outward above and inward below; it gives attachment to the deep fascia of the leg.

The internal border is smooth and rounded above and below, but more prominent in the centre; it commences at the back part of the inner tuberosity, and terminates at the posterior border of the internal malleolus; its upper part gives attachment to the internal lateral ligament of the knee to the extent of about two inches, and to some fibres of the Popliteus muscle; its middle third to some fibres of the Soleus and Flexor longus digitorum muscles.

The external border, or interosseous ridge, is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

The internal surface is smooth, convex, and broader above than below; its upper third, directed forward and inward, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forward as the anterior border; in the rest of its extent it is subcutaneous.

The external surface is narrower than the internal; its upper two-thirds presents a shallow groove for the attachment of the Tibialis anticus muscle; its lower third is smooth, convex, curves gradually forward to the anterior part of the bone, and is covered from within.
outward by the tendons of the following muscles: Tibialis anticus, Extensor proprius hallucis, Extensor longus digitorum.

The posterior surface (Fig. 221) presents, at its upper part, a prominent ridge, the oblique line of the tibia, which extends from the back part of the articular facet for the fibula obliquely downward, to the internal border, at the junction of its upper and middle thirds. It marks the limit for the insertion of the Popliteus muscle, and serves for the attachment of the popliteal fascia and part of the Soleus, Flexor longus digitorum, and Tibialis posticus muscles; the triangular concave surface, above and to the inner side of this line, gives attachment to the Popliteus muscle. The middle third of the posterior surface is divided by a vertical ridge into two lateral halves: the ridge is well marked at its commencement at the oblique line, but becomes gradually indistinct below; the inner and broader half gives attachment to the Flexor longus digitorum, the outer and narrower to part of the Tibialis posticus. The remaining part of the bone presents a smooth surface covered by the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles. Immediately below the oblique line is the medullary foramen, which is directed obliquely downward.

The Lower Extremity, much smaller than the upper, presents five surfaces; it is prolonged downward, on its inner side to a strong process, the internal malleolus. The inferior surface of the bone is quadrilateral, and smooth for articulation with the astragalus. This surface is concave from before backward, and broader in front than behind. It is traversed from before backward by a slight elevation, separating two lateral depressions. It is narrow internally, where the articular surface becomes continuous with that on the inner malleolus. The anterior surface of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles of the toes; its lower margin presents a rough transverse depression, for
the attachment of the anterior ligament of the ankle-joint; the posterior surface presents a superficial groove directed obliquely downward and inward, continuous with a similar groove on the posterior extremity of the astragalus, and serving for the passage of the tendon of the Flexor longus hallucis; the external surface presents a triangular rough depression for the attachment of the inferior interosseous ligament connecting it with the fibula; the lower part of this depression is smooth, covered with cartilage in the recent state, and articulates with the fibula. This surface is bounded by two prominent ridges, continuous above with the interosseous ridge; they afford attachment to the anterior and posterior inferior tibio-fibular ligaments. The internal surface of the lower extremity is prolonged downward to form a strong pyramidal process, flattened from without inward—the inner malleolus. The inner surface of this process is convex and subcutaneous; its outer surface is smooth and slightly concave, and articulates with the astragalus; its anterior border is rough, for the attachment of the anterior fibres of the Deltoid ligament; its posterior border presents a broad and deep groove, directed obliquely downward and inward, which is occasionally double; this groove transmits the tendons of the Tibialis posticus and Flexor longus digitorum muscles. The summit of the internal malleolus is marked by a rough depression behind, for the attachment of the internal lateral ligament of the ankle-joint.

Structure.—Like that of the other long bones. At the junction of the middle and lower third, where the bone is smallest, the wall of the shaft is thicker than in other parts, in order to compensate for the smallness of the calibre of the bone.

Development.—By three centres (Fig. 222): one for the shaft, and one for each extremity. Ossification commences in the centre of the shaft about the seventh week, and gradually extends toward either extremity. The centre for the upper epiphysis appears during the first year; it is flattened in form, and has a thin, tongue-shaped process in front which forms the tubercle. That for the lower epiphysis appears in the second year. The lower epiphysis joins the shaft at about the eighteenth, and the upper one about the twentieth, year. Two additional centres occasionally exist—one for the tongue-shaped process of the upper epiphysis, which forms the tubercle, and one for the inner malleolus.

Articulations.—With three bones: the femur, fibula, and astragalus.

Attachment of Muscles.—To twelve:

- to the inner tuberosity, the Semimembranosus; to the outer tuberosity, the Tibialis anticus and Extensor longus digitorum and Biceps; to the shaft, its internal surface, the Sartorius, Gracilis, and Semitendinosus; to its external surface, the Tibialis anticus; to its posterior surface, the Popliteus, Soleus, Flexor longus digitorum, and Tibialis posticus; to the tubercle, the ligamentum patellae.

Surface Form.—A considerable portion of the tibia is subcutaneous and easily to be felt. At the upper extremity the tuberosities are to be recognized just below the knee. The internal one is broad and smooth, and merges into the subcutaneous surface of the shaft below. The external one is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, may be felt a prominent tubercle for the insertion of the ilio-
The Fibula. (Figs. 220, 221.)

The fibula (fibula, a clasp) is situated at the outer side of the leg. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones; it is placed nearly parallel but behind the level of the tibia. Its upper extremity is small, placed toward the back of the head of the tibia and below the level of the knee-joint, and excluded from its formation; the lower extremity inclines a little forward, so as to be on a plane anterior to that of the upper end, projects below the tibia, and forms the outer ankle. It presents for examination a shaft and two extremities.

The Upper Extremity, or Head, is of an irregular quadrangular form, presenting above a flattened articular facet, directed upward, forward, and inward, for articulation with a corresponding facet on the external tuberosity of the tibia. On the outer side is a thick and rough prominence, continued behind into a pointed eminence, the styloid process, which projects upward from the posterior part of the head. The prominence gives attachment to the tendon of the Biceps muscle and to the long external lateral ligament of the knee, the ligament dividing the tendon into two parts. The summit of the styloid process gives attachment to the short external lateral ligament. The remaining part of the circumference of the head is rough, for the attachment of the anterior superior tibio-fibular ligament, presenting, in front, a tubercle for the attachment of the upper and anterior part of the Peroneus longus; and behind, another tubercle for the attachment of the posterior superior tibio-fibular ligament and the upper fibres of the Soleus muscle.

The shaft presents four borders—the antero-external, the antero-internal, the posterio-external, and the posterio-internal; and four surfaces—anterior, posterior, internal, and external.

The antero-external border commences above in front of the head, runs vertically downward to a little below the middle of the bone, and then, curving somewhat outward, bifurcates so as to embrace the triangular subcutaneous surface immediately above the outer surface of the external malleolus. This border gives attachment to an intermuscular septum, which separates the extensor muscles on the anterior surface of the leg from the Peroneus longus and brevis muscles.

The antero-internal border, or interosseous ridge, is situated close to the inner side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it so as to include a broader space in the lower two-thirds. It commences above just beneath the head of the bone (sometimes it is quite indistinct for about an inch below the head), and terminates below at the apex of a rough triangular surface immediately above the articular facet of the external malleolus. It serves for the attachment of the interosseous membrane, and separates the extensor muscles in front from the flexor muscles behind.

The posterio-external border is prominent; it commences above at the base of the styloid process, and terminates below in the posterior border of the outer malleolus. It is directed outward above, backward in the middle of its course, backward and a little inward below, and gives attachment to an aponeurosis which separates the Peronei muscles on the outer surface of the shaft from the flexor muscles on its posterior surface.
The postero-internal border, sometimes called the oblique line, commences above at the inner side of the head, and terminates by becoming continuous with the antero-internal border or interosseous ridge at the lower fourth of the bone. It is well marked and prominent at the upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posticus from the Soleus above and the Flexor longus hallucis below.

The anterior surface is the interval between the antero-external and antero-internal borders. It is extremely narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the attachment of three muscles, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis.

The external surface is the space between the antero-external and postero-external borders. It is much broader than the preceding, and often deeply grooved, is directed outward in the upper two-thirds of its course, backward in the lower third, where it is continuous with the posterior border of the external malleolus. This surface is completely occupied by the Peroneus longus and brevis muscles.

The internal surface is the interval included between the antero-internal and the postero-internal borders. It is directed inward, and is grooved for the attachment of the Tibialis posticus muscle.

The posterior surface is the space included between the postero-external and the postero-internal borders; it is continuous below with the rough triangular surface above the articular facet of the outer malleolus; it is directed backward above, backward and inward at its middle, directly inward below. Its upper third is rough, for the attachment of the Soleus muscle; its lower part presents a triangular rough surface, connected to the tibia by a strong interosseous ligament, and between these two points the entire surface is covered by the fibers of origin of the Flexor longus hallucis muscle. At about the middle of this surface is the nutrient foramen, which is directed downward.

The Lower Extremity, or external malleolus, is of a pyramidal form, somewhat flattened from without inward, and is longer, and descends lower than the internal malleolus. Its external surface is convex, subcutaneous, and continuous with the triangular (also subcutaneous) surface on the outer side of the shaft. The internal surface presents in front a smooth triangular facet, broader above than below, and convex from above downward, which articulates with a corresponding surface on the outer side of the astragalus. Behind and beneath the articular surface is a rough depression which gives attachment to the posterior fasciculus of the external lateral ligament of the ankle. The anterior border is thick and rough, and marked below by a depression for the attachment of the anterior fasciculus of the external lateral ligament. The posterior border is broad and marked by a shallow groove, for the passage of the tendons of the Peroneus longus and brevis muscles. The summit is rounded, and gives attachment to the middle fasciculus of the external lateral ligament.

In order to distinguish the side to which the bone belongs, hold it with the lower extremity downward and the broad groove for the Peronei tendons backward—i.e., toward the holder: the triangular subcutaneous surface will then be directed to the side to which the bone belongs.

Articulations.—With two bones: the tibia and astragalus.

Development.—By three centres (Fig. 223): one for the shaft, and one for each extremity. Ossification commences in the shaft about the eighth week of fetal life, a little later than in the tibia, and extends gradually toward the extremities. At birth both ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper one and about the fourth year. The lower epiphysis, the first in which ossification commences, becomes united to the shaft about the twentieth year; the upper epiphysis joins about the twenty-fifth year. Ossification appearing first in the lower epiphysis is contrary to the rule which prevails with regard to the commencement of ossification in epiphyses—viz. that that epiphysis toward which the nutrient artery is directed commences
to ossify last; but it follows the rule which prevails with regard to the union of epiphyses, by uniting first.

**Attachment of Muscles.**—To nine: to the head, the Biceps, Soleus, and Peroneus longus; to the shaft, its anterior surface, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis; to the internal surface, the Tibialis posterior; to the posterior surface, the Soleus and Flexor longus hallucis; to the external surface, the Peroneus longus and brevis.

**Surface Form.**—The only parts of the fibula which are to be felt are the head and the lower part of the external surface of the shaft and the external malleolus. The head is to be seen and felt behind and to the outer side of the outer tuberosity of the tibia. It presents a small, prominent triangular eminence slightly above the level of the tubercle of the tibia. The external malleolus presents a narrow elongated prominence, situated on a plane posterior to the internal malleolus and reaching to a lower level. From it may be traced the lower third or half of the external surface of the shaft of the bone in the interval between the Peroneus tertius in front and the other two Peronei tendons behind.

**Surgical Anatomy.**—In fractures of the bones of the leg both bones are usually fractured, but each bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused either by direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is at the junction of the middle and lower third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at rather a higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are usually the result of indirect violence, and the direction of the fracture is from behind, downward, forward, and inward in many cases, but may be downward and outward or downward and backward. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture usually commences as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body whilst the foot is fixed.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia and fibula, like the femur, are frequently the seat of acute necrosis. Chronic abscess is more frequently met with in the cancellous tissue of the head and lower end of the tibia than in any other bone of the body. The abscess is of small size, very chronic, and the result of rarefying osteitis of a localized portion of the cancellous tissue.

The tibia is the bone which is most frequently and most extensively distorted in rickets. It gives way at the junction of the middle and lower third, its weakest part, and presents a curve forward and outward.

**THE FOOT** (Figs. 224, 225).

The skeleton of the Foot consists of three divisions: the Tarsus, Metatarsus, and Phalanges.

**The Tarsus.**

The bones of the Tarsus are seven in number: viz. the calcaneum or os calcis, astragalus, cuboid, navicular, internal, middle, and external cuneiform bones.

**The Calcaneum.**

The Calcaneum, or Os Calcis (calx, the heel), is the largest and strongest of the tarsal bones. It is irregularly cuboidal in form, having its long axis directed forward and outward. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong
Fig. 224.—Bones of the right foot. Dorsal surface.
THE TARSUS: THE CALCANEUM.

lever for the muscles of the calf. It presents for examination six surfaces: superior, inferior, external, internal, anterior, and posterior.

The superior surface is formed behind by the upper aspect of that part of the os calcis which projects backward to form the heel. It varies in length in different individuals; is convex from side to side, concave from before backward, and corresponds above to a mass of adipose substance placed in front of the tendo Achillis. In the middle of the superior surface are two (sometimes three) articular facets, separated by a broad shallow groove, which is directed obliquely forward and outward, and is rough for the attachment of the interosseous ligament connecting the astragalus and os calcis. Of the two articular surfaces, the external is the larger, and situated on the body of the bone; it is of an oblong form, wider behind than in front, and convex from before backward. The internal articular surface is supported on a projecting process of bone, called the lesser process of the calcaneum (sustentaculum tali); it is also oblong, concave longitudinally, and sometimes subdivided into two parts, which differ in size and shape. More anteriorly is seen the upper surface of the greater process, marked by a rough depression for the attachment of numerous ligaments, and a tubercle for the origin of the Extensor brevis digitorum muscle.

The inferior surface is narrow, rough, uneven, wider behind than in front and convex from side to side; it is bounded posteriorly by two tubercles separated by a rough depression; the external, small, prominent, and rounded, gives attachment to part of the Abductor minimi digitii: the internal, broader and larger, for the support of the heel, gives attachment, by its prominent inner margin, to the Abductor hallucis, and in front to the Flexor brevis digitorum muscles; the depression between the tubercles gives attachment to the Abductor minimi digitii and plantar fascia. The rough surface in front of the tubercles gives attachment to the long plantar ligament and to the outer head of the Flexor accessorius muscle; and to a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of it, is attached the short plantar ligament.

The external surface is broad, flat, and almost subcutaneous; it presents near its centre a tubercle, for the attachment of the middle fasciculus of the external lateral ligament. At its upper and anterior part this surface gives attachment to the external calcaneo-astragaloid ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves, separated by an elevated ridge which varies much in size in different bones; it is named the peroneal ridge, and gives attachment to a fibrous process from the external annular ligament. The superior groove transmits the tendon of the Peroneus brevis; the inferior, the tendon of the Peroneus longus.

The internal surface presents a deep concavity, directed obliquely downward and forward, for the transmission of the plantar vessels and nerves into the sole of the foot; it affords attachment to part of the Flexor accessorius muscle. This surface presents an eminence of bone, the lesser process or sustentaculum tali, which projects horizontally inward from its upper and fore part, and to which a slip of the tendon of the Tibialis posticus is attached. This process is concave above, and supports the anterior articular surface of the astragalus; below, it is grooved for the tendon of the Flexor longus hallucis. Its free margin is rough, for the attachment of part of the internal lateral ligament of the ankle-joint.

The anterior surface, of a somewhat triangular form, articulates with the cuboid. It is concave from above downward and outward, and convex in the opposite direction. Its inner border gives attachment to the inferior calcaneonavicular ligament.

The posterior surface is rough, prominent, convex, and wider below than above. Its lower part is rough, for the attachment of the tendo Achillis and of the Plantaris muscle; its upper part is smooth, and is covered by a bursa which separates the tendon from the bone.

Articulations.—With two bones: the astragalus and cuboid.
Attachment of Muscles.—To eight: part of the Tibialis posticus, the tendo
Achillis, Plantaris, Abductor hallucis, Abductor minimi digiti, Flexor brevis digitorum, Flexor accessorius, and Extensor brevis digitorum.

The Astragalus.

The Astragalus (ἀστράγαλος; a die) is the largest of the tarsal bones, next to the os calcis. It occupies the middle and upper part of the tarsus, supporting the tibia above, articulating with the malleoli on either side, resting below upon the os calcis, and joined in front to the navicular. This bone may easily be recognized by its large rounded head, by the broad articular facet on its upper convex surface, or by the two articular facets separated by a deep groove on its under concave surface. It presents six surfaces for examination.

The superior surface presents, behind, a broad smooth trochlear surface for articulation with the tibia. The trochlea is broader in front than behind, convex from before backward, slightly concave from side to side; in front of it is the upper surface of the neck of the astragalus, rough for the attachment of ligaments. The inferior surface presents two articular facets separated by a deep groove. The groove runs obliquely forward and outward, becoming gradually broader and deeper in front; it corresponds with a similar groove upon the upper surface of the os calcis, and forms, when articulated with that bone, a canal, filled up in the recent state by the interosseous calcaneo-astragaloid ligament. Of the two articular facets, the posterior is the larger, of an oblong form and deeply concave from side to side; the anterior, although nearly of equal length, is narrower, of an elongated oval form, convex longitudinally, and often subdivided into two by an elevated ridge; of these, the posterior articulates with the lesser process of the os calcis; the anterior, with the upper surface of the inferior calcaneo-navicular ligament. The internal surface presents at its upper part a pear-shaped articular facet for the inner malleolus, continuous above with the trochlear surface; below the articular surface is a rough depression, for the attachment of the deep portion of the internal lateral ligament. The external surface presents a large triangular facet, concave from above downward for articulation with the external malleolus; it is continuous above with the trochlear surface; and in front of it is a rough depression for the attachment of the anterior fasciculus of the external lateral ligament of the ankle-joint. The anterior surface, convex and rounded, forms the head of the astragalus; it is smooth, of an oval form, and directed obliquely inward and downward; it articulates with the navicular. On its under surface is a small facet, continuous in front with the articular surface of the head, and behind with the smaller facet for the os calcis. This rests on the inferior calcaneo-navicular ligament, being separated from it by the synovial membrane, which is prolonged from the anterior calcaneo-astragaloid joint to the astragalo-navicular joint. The head is surrounded by a constricted portion, the neck of the astragalus. The posterior surface is narrow, and traversed by a groove, which runs obliquely downward and inward, and transmits the tendon of the Flexor longus hallucis, external to which is a prominent tubercle, to which the posterior fasciculus of the external lateral ligament is attached. To the inner side of the groove is a second, but less marked tubercle.

To ascertain to which foot the bone belongs, hold it with the broad articular surface upward, and the rounded head forward; the lateral triangular articular surface for the external malleolus will then point to the side to which the bone belongs.

Articulations.—With four bones: tibia, fibula, os calcis, and navicular.

The Cuboid.

The Cuboid (κύδος; a cube; κύδος, like) bone is placed on the outer side of the foot, in front of the os calcis, and behind the fourth and fifth metatarsal bones. It is of a pyramidal shape, its base being directed upward and inward, its apex downward and outward. It may be distinguished from the other tarsal bones by...
the existence of a deep groove on its under surface, for the tendon of the Peroneus longus muscle. It presents for examination six surfaces: three articular and three non-articular.

The non-articular surfaces are the superior, inferior, and external. The superior or dorsal surface, directed upward and outward, is rough, for the attachment of numerous ligaments. The inferior or plantar surface presents in front a deep groove, which runs obliquely from without, forward and inward; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which is attached the long calcaneo-cuboid ligament. The ridge terminates externally in an eminence, the tuberosity of the cuboid, the surface of which presents a convex facet, for articulation with the sesamoid bone of the tendon contained in the groove. The surface of bone behind the groove is rough, for the attachment of the short plantar ligament, a few fibres of the Flexor brevis hallucis, and a fasciculus from the tendon of the Tibialis posticus. The external surface, the smallest and narrowest of the three, presents a deep notch formed by the commencement of the peroneal groove.

The articular surfaces are the posterior, anterior, and internal. The posterior surface is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the os calcis. The anterior, of smaller size, but also irregularly triangular, is divided by a vertical ridge into two facets: the inner one, quadrilateral in form, articulates with the fourth metatarsal bone; the outer one, larger and more triangular, articulates with the fifth metatarsal. The internal surface is broad, rough, irregularly quadrilateral, presenting at its middle and upper part a smooth oval facet, for articulation with the external cuneiform bone; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interossseous ligaments.

To ascertain to which foot the bone belongs, hold it so that its under surface, marked by the peroneal groove, looks downward, and the large concavo-convex articular surface backward toward the holder: the narrow non-articular surface, marked by the commencement of the peroneal groove, will point to the side to which the bone belongs.

Articulations.—With four bones: the os calcis, external cuneiform, and the fourth and fifth metatarsal bones; occasionally with the navicular.

Attachment of Muscles.—Part of the Flexor brevis hallucis and a slip from the tendon of the Tibialis posticus.

The Navicular.

The Navicular or Scaphoid bone is situated at the inner side of the tarsus, between the astragalus behind and the three cuneiform bones in front. It may be distinguished by its form, being concave behind, convex and subdivided into three facets in front.

The anterior surface, of an oblong form, is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The posterior surface is oval, concave, broader externally than internally, and articulates with the rounded head of the astragalus. The superior surface is convex from side to side, and rough for the attachment of ligaments. The inferior is irregular, and also rough for the attachment of ligaments. The internal surface presents a rounded tubercular eminence, the tuberosity of the navicular, the lower part of which projects, and gives attachment to part of the tendon of the Tibialis posticus. The external surface is rough and irregular, for the attachment of ligamentous fibres, and occasionally presents a small facet for articulation with the cuboid bone.

To ascertain to which foot the bone belongs, hold it with the concave articular surface backward, and the convex dorsal surface upward; the external surface—i. e. the surface opposite the tubercle—will point to the side to which the bone belongs.
Articulations.—With four bones: astragalus and three cuneiform; occasionally also with the cuboid.

Attachment of Muscles.—Part of the Tibialis posticus.

The Cuneiform Bones.

The Cuneiform Bones have received their name from their wedge-like shape (cuneus, a wedge; forma, likeness). They form, with the cuboid, the anterior row of the tarsus, being placed between the navicular behind, the three innermost metatarsal bones in front, and the cuboid externally. They are called the first, second, and third, counting from the inner to the outer side of the foot, and, from their position, internal, middle, and external.

The Internal Cuneiform is the largest of the three. It is situated at the inner side of the foot, between the navicular behind and the base of the first metatarsal in front. It may be distinguished, from the other two by its large size, and its more irregular, wedge-like form. Without the others, it may be known by the large kidney-shaped anterior articulating surface and by the prominence on the inferior or plantar surface for the attachment of the Tibialis posticus. It presents for examination six surfaces.

The internal surface is subcutaneous, and forms part of the inner border of the foot; it is broad, quadrilateral, and presents at its anterior inferior angle a smooth oval facet, into which the tendon of the Tibialis anticus is partially inserted; in the rest of its extent it is rough, for the attachment of ligaments. The external surface is concave, presenting, along its superior and posterior borders, a narrow reversed L-shaped surface for articulation with the middle cuneiform behind, and second metatarsal bone in front; in the rest of its extent it is rough for the attachment of ligaments and part of the tendon of the Peroneus longus. The anterior surface, kidney-shaped, much larger than the posterior, articulates with the metatarsal bone of the great toe. The posterior surface is triangular, concave, and articulates with the innermost and largest of the three facets on the anterior surface of the navicular. The inferior or plantar surface is rough, and presents a prominent tuberosity at its back part for the attachment of part of the tendon of the Tibialis posticus. It also gives attachment in front to part of the tendon of the Tibialis anticus. The superior surface is the narrow-pointed end of the wedge, which is directed upward and outward; it is rough for the attachment of ligaments.

To ascertain to which side the bone belongs, hold it so that its superior narrow edge looks upward, and the long, kidney-shaped, articular surface forward; the external surface, marked by its vertical and horizontal articular facets, will point to the side to which it belongs.

Articulations.—With four bones: navicular, middle cuneiform, first and second metatarsal bones.

Attachment of Muscles.—To three: the Tibialis anticus and posticus, and Peroneus longus.

The Middle Cuneiform, the smallest of the three, is of very regular wedge-like form. The broad extremity being placed upward, the narrow end downward. It is situated between the other two bones of the same name, and articulates with the navicular behind and the second metatarsal in front. It may be distinguished from the external cuneiform bone, which it much resembles in general appearance, by the articular facet. of angular form, which runs round the upper and back part of its inner surface; and if the two bones from the same foot are together, the middle cuneiform is much the smaller.

The anterior surface, triangular in form and narrower than the posterior, articulates with the base of the second metatarsal bone. The posterior surface, also triangular, articulates with the navicular. The internal surface presents a reversed L-shaped articular facet, running along the superior and posterior borders, for articulation with the internal cuneiform, and is rough in the rest of its extent for the attachment of ligaments. The external surface presents posteriorly a smooth facet for articulation with the external cuneiform bone. The superior
surface forms the base of the wedge; it is quadrilateral, broader behind than in front, and rough for the attachment of ligaments. The inferior surface, pointed and tubercular, is also rough for ligamentous attachment and for the insertion of a slip from the tendon of the Tibialis posticus.

To ascertain to which foot the bone belongs, hold its superior or dorsal surface upward, the broadest edge being toward the holder: the smooth facet (limited to the posterior border) will then point to the side to which it belongs.

Articulations.—With four bones: navicular, internal and external cuneiform, and second metatarsal bone.

Attachment of Muscles.—A slip from the tendon of the Tibialis posticus is attached to this bone.

The External Cuneiform, intermediate in size between the two preceding, is of a very regular wedge-like form, the broad extremity being placed upward, the narrow end downward. It occupies the centre of the front row of the tarsus between the middle cuneiform internally, the cuboid externally, the navicular behind, and the third metatarsal in front. It is distinguished from the internal cuneiform bone by its more regular wedge-like shape and by the absence of the kidney-shaped articular surface: from the middle cuneiform, by the absence of the reversed L-shaped facet, and by the two articular facets which are present on both its inner and outer surfaces. It has six surfaces for examination.

The anterior surface, triangular in form, articulates with the third metatarsal bone. The posterior surface articulates with the most external facet of the navicular, and is rough below for the attachment of ligamentous fibres. The internal surface presents two articular facets, separated by a rough depression; the anterior one, sometimes divided into two, articulates with the outer side of the base of the second metatarsal bone; the posterior one skirts the posterior border and articulates with the middle cuneiform; the rough depression between the two gives attachment to an interosseous ligament. The external surface also presents two articular facets, separated by a rough non-articular surface; the anterior facet, situated at the superior angle of the bone, is small, and articulates with the inner side of the base of the fourth metatarsal; the posterior and larger one articulates with the cuboid; the rough, non-articular surface serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another, and covered by a prolongation of the same cartilage; the facets for articulation with the middle cuneiform and navicular are also continuous, but that for articulation with the cuboid is usually separate. The superior or dorsal surface is of an oblong square form, its posterior external angle being prolonged backward. The inferior or plantar surface is an obtuse rounded margin, and serves for the attachment of part of the tendon of the Tibialis posticus, part of the Flexor brevis hallucis, and ligaments.

To ascertain to which side the bone belongs, hold it with the broad dorsal surface upward, the prolonged edge backward; the separate articular facet for the cuboid will point to the proper side.

Articulations.—With six bones: the navicular, middle cuneiform, cuboid, and second, third, and fourth metatarsal bones.

Attachment of Muscles.—To two: part of the Tibialis posticus, and Flexor brevis hallucis.

The Metatarsal Bones.

The Metatarsal Bones are five in number; they are long bones, and present for examination a shaft and two extremities.

Common Characters.—The shaft is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is slightly curved longitudinally, so as to be concave below, slightly convex above. The posterior extremity, or base, is wedge-shaped, articulating by its terminal surface with the tarsal bones, and by its lateral surfaces with the contiguous metatarsal bones, its dorsal and plantar surfaces being rough for the attachment of ligaments. The anterior extremity,
or head, presents a terminal rounded articular surface, oblong from above downward and extending farther backward below than above. Its sides are flattened, and present a depression, surmounted by a tubercle, for ligamentous attachment. Its under surface is grooved in the middle line for the passage of the Flexor tendon, and marked on each side by an articular eminence continuous with the terminal articular surface.

**Peculiar Characters.**—The First is remarkable for its great thickness, but is the shortest of all the metatarsal bones. The shaft is strong and of well-marked prismatic form. The posterior extremity presents at times a lateral articular facet for the second metatarsal; its terminal articular surface is of large size, kidney-shaped; its circumference is grooved, for the tarso-metatarsal ligaments, and internally gives attachment to part of the tendon of the Tibialis anticus: its inferior angle presents a rough oval prominence for the insertion of the tendon of the Peroneus longus. The head is of large size; on its plantar surface are two grooved facets, over which glide sesamoid bones; the facets are separated by a smooth elevated ridge.

This bone is known by the single kidney-shaped articular surface on its base, the deeply grooved appearance of the plantar surface of its head, and its great thickness relatively to its length. When it is placed in its natural position, the concave border of the kidney-shaped articular surface on its base points to the side to which the bone belongs.

The Second is the longest and largest of the remaining metatarsal bones, being prolonged backward into the recess formed between the three cuneiform bones. Its tarsal extremity is broad above, narrow and rough below. It presents four articular surfaces: one behind, of a triangular form, for articulation with the middle cuneiform; one at the upper part of its internal lateral surface, for articulation with the internal cuneiform; and two on its external lateral surface, a posterior and anterior, separated by a vertical ridge. Each of these external articular surfaces is divided by a rough depression into two parts; the two anterior facets articulate with the third metatarsal; the two posterior (sometimes continuous) with the external cuneiform. Occasionally, in front of and below the facet for the internal cuneiform, is found an indistinct facet for the first metatarsal.

The facets on the tarsal extremity of the second metatarsal bone serve at once to distinguish it from the rest, and to indicate the foot to which it belongs. The fact that the two posterior subdivisions of the external facets sometimes run into one should not be forgotten.

The Third articulates behind, by means of a triangular smooth surface, with the external cuneiform; on its inner side, by two facets, with the second metatarsal; and on its outer side, by a single facet, with the fourth metatarsal. The latter facet is of circular form and situated at the upper angle of the base.

The third metatarsal is known by its having at its tarsal end two undivided facets on the inner side, and a single facet on the outer. This distinguishes it from the second metatarsal, in which the two facets, found on one side of its tarsal end, are each subdivided into two. The single facet (when the bone is put in its natural position) is on the side to which the bone belongs.

The Fourth is smaller in size than the preceding; its tarsal extremity presents a terminal quadrilateral surface, for articulation with the cuboid; a smooth facet on the inner side, divided by a ridge into an anterior portion for articulation with the third metatarsal, and a posterior portion for articulation with the external cuneiform; on the outer side a single facet, for articulation with the fifth metatarsal.

The fourth metatarsal is known by its having a single facet on either side of the tarsal extremity, that on the inner side being divided into two parts. If this subdivision be not recognizable, the fact that its tarsal end is bent somewhat outward will indicate the side to which it belongs.

The Fifth is recognized by the tubercular eminence on the outer side of its base. It articulates behind, by a triangular surface cut obliquely from without inward, with the cuboid, and internally with the fourth metatarsal.
The projection on the outer side of this bone at its tarsal end at once distinguishes it from the others, and points to the side to which it belongs.

Articulations.—Each bone articulates with the tarsal bones by one extremity, and by the other with the first row of phalanges. The number of tarsal bones with which each metatarsal articulates is one for the first, three for the second, one for the third, two for the fourth, and one for the fifth.

Attachment of Muscles.—To the first metatarsal bone, three: part of the Tibialis anticus, the Peroneus longus, and First dorsal interosseous. To the second, four: the Adductor obliquus hallucis and First and Second dorsal interosseous, and a slip from the tendon of the Tibialis posticus, and occasionally a slip from the Peroneus longus. To the third, five: the Adductor obliquus hallucis, Second and Third dorsal, and First plantar interosseous, and a slip from the tendon of the Tibialis posticus. To the fourth, five: the Adductor obliquus hallucis, Third and Fourth dorsal, and Second plantar interosseous, and a slip from the tendon of the Tibialis posticus. To the fifth, six: the Peroneus brevis, Peroneus tertius, Flexor brevis minimi digiti, Adductor transversus hallucis, Fourth dorsal, and Third plantar interosseous.

The Phalanges.

The Phalanges of the foot, both in number and general arrangement, resemble those in the hand; there being two in the great toe and three in each of the other toes.

The phalanges of the first row resemble closely those of the hand. The shaft is compressed from side to side, convex above, concave below. The posterior extremity is concave; and the anterior extremity presents a trochlear surface, for articulation with the second phalanges.

The phalanges of the second row are remarkably small and short, but rather broader than those of the first row.

The ungual phalanges in form resemble those of the fingers; but they are smaller, flattened from above downward, presenting a broad base for articulation with the second row, and an expanded extremity for the support of the nail and end of the toe.

Articulation.—The first row, with the metatarsal bones behind and second phalanges in front; the second row of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row of the four outer toes, with the second phalanges.

Development of the Foot (Fig. 226).

The Tarsal bones are each developed by a single centre, excepting the os calcis, which has an epiphysis for its posterior extremity. The centres make their appearance in the following order: os calcis, at the sixth month of fetal life; astragalus,

1 Except the second phalanx of the fifth toe, which receives no slip from the Extensor brevis digitorum.
about the seventh month; cuboid, at the ninth month; external cuneiform, during the first year; internal cuneiform in the third year; middle cuneiform and navicular in the fourth year. The epiphysis for the posterior tuberosity of the os calcis appears at the tenth year, and unites with the rest of the bone soon after puberty.

The Metatarsal bones are each developed by two centres: one for the shaft and one for the digital extremity in the four outer metatarsal; one for the shaft and one for the base in the metatarsal bone of the great toe.\(^1\) Ossification commences in the centre of the shaft about the ninth week, and extends toward either extremity. The centre in the proximal end of the first metatarsal bone appears about the third year, the centre in the distal end of the other bones between the fifth and eighth years; they become joined between the eighteenth and twentieth years.

The Phalanges are developed by two centres for each bone: one for the shaft and one for the metatarsal extremity.

**Construction of the Foot as a Whole.**

The foot is constructed on the same principles as the hand, but modified to form a firm basis of support for the rest of the body when in the erect position. It

---

\(^{1}\) As was noted in the first metacarpal bone, so in the first metatarsal, there is often to be observed a tendency to the formation of a second epiphysis in the distal extremity. (See footnote, p. 274).
is more solidly constructed, and its component parts are less movable on each other than in the hand. This is especially the case with the great toe, which has to assist in supporting the body, and is therefore constructed with greater solidity; it lies parallel with the other toes, and has a very limited degree of mobility, whereas the thumb, which is occupied in numerous and varied movements, is constructed in such a manner as to permit of great mobility. Its metacarpal bone is directed away from the others, so as to form an acute angle with the second, and it enjoys a considerable range of motion at its articulation with the carpus. The foot is placed at right angles to the leg—a position which is almost peculiar to man, and has relation to the erect position which he maintains. In order to allow of its supporting the weight of the whole body in this position with the least expenditure of material, it is constructed in the form of an arch. This arch is not, however, made up of two equal limbs. The hinder one, which is made up of the os calcis and the posterior part of the astragalus, is about half the length of the anterior limb, and measures about three inches. The anterior limb consists of the rest of the tarsal and the metatarsal bones, and measures about six inches. It may be said to consist of two parts, an inner segment made up of the head of the astragalus, the navicular, the three cuneiform, and the three inner metatarsal bones; and an outer segment composed of the cuboid and the two outer metatarsal bones. The summit of the arch is at the superior articular surface of the astragalus; and its two extremities—that is to say, the two points on which the arch rests in standing—are the tubercles on the under surface of the os calcis posteriorly, and the heads of the metatarsal bones anteriorly. The weakest part of the arch is the joint between the astragalus and scaphoid, and here it is more liable to yield in those who are overweighted, and in those in whom the ligaments which complete and preserve the arch are relaxed. This weak point in the arch is braced on its concave surface by the inferior calcaneo-navicular ligament, which is more elastic than most other ligaments, and thus allows the arch to yield from jars or shocks applied to the anterior portion of the foot and quickly restores it to its pristine condition. This ligament is supported on its under surface by the tendon of the Tibialis posticus muscle, which is spread out into a fan-shaped insertion, and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it.

In addition to this longitudinal arch the foot presents a transverse arch, at the anterior part of the tarsus and hinder part of the metatarsus. This, however, can scarcely be described as a true arch, but presents more the character of a half-dome. The inner border of the central portion of the longitudinal arch is elevated from the ground, and from this point the bones arch over to the outer border, which is in contact with the ground, and, assisted by the longitudinal arch, produce a sort of rounded niche on the inner side of the foot, which gives the appearance of a transverse as well as a longitudinal arch.

The arch of the foot, from the point of the heel to the toes, is not quite straight, but is directed a little outward, so that the inner border is a little convex and the outer border concave. This disposition of the bones becomes more marked when the longitudinal arch of the foot is lost, as in the disease known under the name of "flat-foot."

**Surface Form.**—On the dorsum of the foot the individual bones are not to be distinguished with the exception of the head of the astragalus, which forms a rounded projection in front of the ankle-joint when the foot is forcibly extended. The whole surface forms a smooth convex outline, the summit of which is the ridge formed by the head of the astragalus, the navicular, the middle cuneiform, and the second metatarsal bone; from this it gradually inclines outward and more rapidly inward. On the inner side of the foot, the internal tuberosity of the os calcis and the ridge separating the inner from the posterior surface of the bone may be felt most posteriorly. In front of this, and below the internal malleolus, may be felt the projection of the sustentaculum tali. Passing forward is the well-marked tuberosity of the navicular bone, situated about an inch or an inch and a quarter in front of the internal malleolus. Further toward the front, the ridge formed by the base of the first metatarsal bone can be obscurely felt, and from this the shaft of the bone can be traced to the expanded head articulating with the base of the first phalanx of the great toe. Immediately beneath the base of this phalanx, the
internal sesamoid bone is to be felt. Lastly, the expanded ends of the bones forming the last joint of the great toe are to be felt. On the outer side of the foot the most posterior bony point is the outer tuberosity of the os calcis, with the ridge separating the posterior from the outer surface of the bone. In front of this the greater part of the external surface of the os calcis is subcutaneous; on it, below and in front of the external malleolus, may be felt the peroneal ridge, when this process is present. Farther forward, the base of the fifth metatarsal bone forms a prominent and well-defined landmark, and in front of this the shaft of the bone, with its expanded head, and the base of the first phalanx may be defined. The sole of the foot is almost entirely covered by soft parts, so that but few bony parts are to be made out, and these somewhat obscurely. The hinder part of the under surface of the os calcis and the heads of the metatarsal bones, with the exception of the first, which is concealed by the sesamoid bones, may be recognized.

Surgical Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface and joined together by very strong ligaments, which serve to break the force of violence applied to this part of the body. When fracture does occur, these bones, being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence. And having only a very scanty amount of soft parts over them, the fractures are very often compound, and amputation is frequently necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group, that is, of the calcaneum and astragalus, are most frequently produced by falls from a height on to the feet; though fracture of the os calcis may be caused by direct violence or by muscular action. The posterior part of the bone, that is, the part behind the articular surfaces, is almost always the seat of the fracture, though some few cases of fracture of the sustentaculum tali and of vertical fracture between the two articulating facets have been recorded. The neck of the astragalus, being the weakest part of the bone, is most frequently fractured, though fractures may occur in any part and almost in any direction, either associated or not with fracture of other bones.

In cases of club-foot, especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is especially the case in congenital equino-varus, in which the astragalus, particularly about the head, becomes twisted and atrophied, and a similar condition may be present in the other bones. The astragalus is a cancellous bone. The tarsal bones are peculiarly liable to become the seat of tubercular caries from comparatively trivial injuries. There are several reasons to account for this. They are composed of a delicate cancellated structure, surrounded by intricate synovial membranes. They are situated at the farthest point from the central organ of the circulation and exposed to vicissitudes of temperature; and, moreover, on their dorsal surface are thinly clad with soft parts which have but a scanty blood-supply. And finally, after slight injuries, they are not maintained in a condition of rest to the same extent as similar injuries in some other parts of the body. Caries of the calcaneum and astragalus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, in consequence of the disease spreading through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the whole or a part of the foot is frequently required either for injury or disease. The principal amputations are as follow: (1) Syme’s: amputation at the ankle-joint by a heel-flap, with removal of the malleoli and sometimes a thin slice from the lower end of the tibia. (2) Roux’s: amputation at the ankle-joint by a large internal flap. (3) Pirogoff’s amputation: removal of the whole of the tarsal bones, except the posterior part of the os calcis and a thin slice from the tibia and fibula including the two malleoli. The swn surface of the os calcis is then turned up and united to the similar surface of the tibia. (4) Subastragaloid amputation: removal of the foot below the astragalus through the joint between it and the os calcis. This operation has been modified by Hancock, who leaves the posterior third of the os calcis and turns up against the denuded surface of the astragalus. This latter operation is of doubtful utility; but rarely performed. (5) Chopart’s or medio-tarsal: removal of the anterior part of the foot with all the tarsal bones except the os calcis and astragalus; disarticulation being effected through the joints between the seaphoid and cuboid in front, and the astragalus and os calcis behind. (6) Lisfranc’s: amputation of the anterior part of the foot through the tarso-metatarsal joints. This has been modified by Hey, who disarticulated through the joints of the four outer metatarsal bones with the tarsus, and sawed off the projecting internal cuneiform; and by Skey, who sawed off the base of the second metatarsal bone and disarticulated the others.

The bones of the tarsus occasionally require removal individually. This is especially the case with the astragalus and os calcis for disease limited to the one bone, or again the astragalus may require excision in cases of subastragaloid dislocation, or, as recommended by Mr. Land, in cases of inveterate talipes. The cuboid has been removed for the same reason by Mr. Solly. But both these latter operations have fallen very much into disuse, and have been superseded by resection of a wedge-shaped piece of bone from the outer side of the tarsus. Finally, Mickulicz and Watson have devised operations for the removal of more extensive portions of the tarsus. Mickulicz’s operation consists in the removal of the os calcis and astragalus, along
with the articular surfaces of the tibia and fibula, and also of the scaphoid and cuboid. The remaining portion of the tarsus is then brought into contact with the sawn surfaces of the tibia and fibula, and fixed there. The result is a position of the shortened foot resembling talipes equinus. Watson's operation is adapted to those cases where the disease is confined to the anterior tarsal bones. By two lateral incisions he saws through the bases of the metatarsal bones in front and opens up the joints between the scaphoid and astragalus, and the cuboid and os calcis, and removes the intervening bones.

The metatarsal bones and phalanges are nearly always broken by direct violence, and in the majority of cases the injury is the result of severe crushing accidents, necessitating amputation. The metatarsal bones and especially the one of the great toe, are frequently diseased, either in tubercular subjects or in perforating ulcer of the foot.

**Sesamoid Bones.**

These are small rounded masses, cartilaginous in early life, osseous in the adult, which are developed in those tendons which exert a great amount of pressure upon the parts over which they glide. It is said that they are more commonly found in the male than in the female, and in persons of an active muscular habit than in those who are weak and debilitated. They are invested throughout their whole surface by the fibrous tissue of the tendon in which they are found, excepting upon that side which lies in contact with the part over which they play, where they present a free articular facet. They may be divided into two kinds; those which glide over the articular surfaces of joints, and those which play over the cartilaginous facets found on the surfaces of certain bones.

The sesamoid bones of the joints in the upper extremity, are two on the palmar surface of the metacarpo-phalangeal joint in the thumb, developed in the tendons of the Flexor brevis pollicis; occasionally one or two opposite the metacarpo-phalangeal articulations of the fore and little fingers; and, still more rarely, one opposite the same joints of the third and fourth fingers. In the lower extremity, the patella, which is developed in the tendon of the Quadriceps extensor; two small sesamoid bones, found in the tendons of the Flexor brevis hallucis, opposite the metatarso-phalangeal joint of the great toe; and occasionally one in the metatarso-phalangeal joint of the second toe, the little toe, and, still more rarely, the third and fourth toes.

Those found in the tendons which glide over certain bones occupy the following situations: one sometimes found in the tendon of the Biceps cubiti, opposite the tuberosity of the radius; one in the tendon of the Peroneus longus, where it glides through the groove in the cuboid bone; one appears late in life in the tendon of the Tibialis anticus, opposite the smooth facet of the internal cuneiform bone; one is found in the tendon of the Tibialis posticus, opposite the inner side of the head of the astragalus; one in the outer head of the Gastrocnemius, behind the outer condyle of the femur; and one in the conjoined tendon of the Psoas and Iliacus, where it glides over the os pubis. Sesamoid bones are found occasionally in the tendon of the Gluteus maximus, as it passes over the great trochanter, and in the tendons which wind round the inner and outer malleoli.
THE ARTICULATIONS.

The various bones of which the Skeleton consists are connected together at different parts of their surfaces, and such a connection is designated by the name of Joint or Articulation. If the joint is immovable, as between the cranial and most of the facial bones, the adjacent margins of the bones are applied in almost close contact, a thin layer of fibrous membrane, the sutural ligament, and, at the base of the skull, in certain situations, a thin layer of cartilage, being interposed. Where slight movement is required, combined with great strength, the osseous surfaces are united by tough and elastic fibro-cartilages, as in the joints between the bodies of the vertebrae and interpubic articulations; but in the movable joints the bones forming the articulation are generally expanded at the ends for greater convenience of mutual connection, covered by cartilage, held together by strong bands or capsules of fibrous tissue called ligaments, and partially lined by a membrane, the synovial membrane, which secretes a fluid to lubricate the various parts of which the joint is formed; so that the structures which enter into the formation of a joint are bone, cartilage, fibro-cartilage, ligament, and synovial membrane.

Bone constitutes the fundamental element of all the joints. In the long bones the extremities are the parts which form the articulations; they are generally somewhat enlarged, consisting of spongy cancellous tissue, with a thin coating of compact substance. In the flat bones the articulations usually take place at the edges, and, in the short bones at various parts of their surface. The layer of compact bone which forms the articular surface, and to which the cartilage is attached, is called the articular lamella. It is of a white color, extremely dense, and varies in thickness. Its structure differs from ordinary bone-tissue in this respect, that it contains no Haversian canals, and its lacunae are much larger than in ordinary bone and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently more dense and firmer than ordinary bone, and is evidently designed to form a firm and unyielding support for the articular cartilage.

The cartilage, which covers the articular surfaces of bone, and is called the articular, will be found described, with the other varieties of cartilage, in the section on General Anatomy (page 51).

Ligaments consist of bands of various forms, serving to connect together the articular extremities of bones, and composed mainly of bundles of white fibrous tissue placed parallel with, or closely interlaced with, one another, and presenting a white, shining, silvery aspect. A ligament is pliant and flexible, so as to allow of the most perfect freedom of movement, but strong, tough, and inextensible, so as not readily to yield under the most severely applied force; it is consequently well adapted to serve as the connecting medium between the bones. Some ligaments consist entirely of yellow elastic tissue, as the ligamenta subflava, which connect together the adjacent arches of the vertebrae and the ligamentum nuchae in the lower animals. In these cases it will be observed that the elasticity of the ligament is intended to act as a substitute for muscular power.

Synovial membrane is a thin, delicate membrane of connective tissue, with branched connective-tissue corpuscles. Its secretion is thick, viscid, and glairy, like the white of egg, and is hence termed synovia. The synovial membranes found in the body admit of subdivision into three kinds—articular, bursal, and vaginal.

The articular synovial membranes are found in all the freely movable joints. In the foetus this membrane is said, by Toynbee, to be continued over the surface
of the cartilages; but in the adult it is wanting, excepting at their circumference, upon which it encroaches for a short distance, and to which it is firmly attached; it then invests the inner surface of the capsular or other ligaments enclosing the joint, and is reflected over the surface of any tendons passing through its cavity, as the tendon of the Popliteus in the knee and the tendon of the Biceps in the shoulder. Hence the articular synovial membrane may be regarded as a short wide tube, attached by its open ends to the margins of the articular cartilages, and covering the inner surface of the various ligaments which connect the articular surfaces, so that along with the cartilages it completely encloses the joint-cavity. In some of the joints the synovial membrane is thrown into folds, which pass across the cavity. They are called synovial ligaments, and are especially distinct in the knee. In other joints there are flattened folds, subdivided at their margins into fringe-like processes, the vessels of which have a convoluted arrangement. These latter generally project from the synovial membrane near the margin of the cartilage and lie flat upon its surface. They consist of connective tissue covered with endothelium, and contain fat-cells in variable quantities, and, more rarely, isolated cartilage-cells. The larger folds often contain considerable quantities of fat. They were described by Clopton Havers as mucilaginous glands, and as the source of the synovial secretion. Under certain diseased conditions similar processes are found covering the entire surface of the synovial membrane, forming a mass of pedunculated fibro-fatty growths which project into the joint. Similar structures are also found in some of the bursal and vaginal synovial membranes.

The **bursal synovial membranes** are found interposed between surfaces which move upon each other, producing friction, as in the gliding of a tendon or of the integument over projecting bony surfaces. They admit of subdivision into two kinds, the **bursa mucosa** and the **bursa synovia**. The **bursa mucosa** are large, simple, or irregular cavities in the subcutaneous areolar tissue, enclosing a clear viscid fluid. They are found in various situations, as between the integument and the front of the patella, over the olecranon, the malleoli, and other prominent parts. The **bursa synovia** are found interposed between muscles or tendons as they play over projecting bony surfaces, as between the Glutei muscles and the surface of the great trochanter. They consist of a thin wall of connective tissue, partially covered by patches of cells, and contain a viscid fluid. Where one of these exists in the neighborhood of a joint, it usually communicates with its cavity, as is generally the case with the bursa between the tendon of the Psoas and Iliacus and the capsular ligament of the hip, or the one interposed between the under surface of the Subscapularis and the neck of the scapula.

The **vaginal synovial membranes** (**synovial sheaths**) serve to facilitate the gliding of tendons in the osseo-fibrous canals through which they pass. The membrane is here arranged in the form of a sheath, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the contained tendon, the space between the two free surfaces of the membrane being partially filled with synovia. These sheaths are chiefly found surrounding the tendons of the flexor and extensor muscles of the fingers and toes as they pass through the osseo-fibrous canals in the hand or foot.

**Synovia** is a transparent, yellowish-white or slightly reddish fluid, viscid like the white of egg, having an alkaline reaction and slightly saline taste. It consists, according to Frerichs, in the ox, of 94.85 water, 0.56 mucus and epithelium, 0.07 fat, 3.51 albumen and extractive matter, and 0.99 salts.

The articulations are divided into three classes: **synarthrosis**, or immovable; **amphiarthrosis**, or mixed; and **diarthrosis**, or movable joints.

1. **Synarthrosis.** Immovable Articulations.

**Synarthrosis** includes all those articulations in which the surfaces of the bones are in almost direct contact, fastened together by an intervening mass of connective tissue, and in which there is no appreciable motion, as the joints between the bones
of the cranium and face, excepting those of the lower jaw. The varieties of synarthrosis are four in number: Sutura, Schindylesis, Gomphosis, and Synchondrosis.

Sutura (a seam) is that form of articulation where the contiguous margins of flat bones are united by a thin layer of fibrous tissue. It is met with only in the skull. Where the articulating surfaces are connected by a series of processes and indentations interlocked together, it is termed sutura vera, of which there are three varieties: sutura dentata, serrata, and limbosa. The surfaces of the bones are not in direct contact, being separated by a layer of membrane continuous externally with the pericranium, internally with the dura mater. The sutura dentata (dens, a tooth) is so called from the tooth-like form of the projecting articular processes, as in the suture between the parietal bones. In the sutura serrata (serra, a saw) the edges of the two bones forming the articulation are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the sutura limbossa (limbus, a selvage), besides the dentated processes, there is a certain degree of bevelling of the articular surfaces, so that the bones overlap one another, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed the false sutura (sutura notba), of which there are two kinds: the sutura squamosa (squama, a scale), formed by the overlapping of two contiguous bones by broad bevelled margins, as in the squamo-parietal (squamous) suture; and the sutura harmonia (qumia, a joining together), where there is simple apposition of two contiguous rough bony surfaces, as in the articulation between the two superior maxillary bones or of the horizontal plates of the palate bones.

Schindylesis (αγωνύλης, a fissure) is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminae in another bone; as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the superior maxillary and palate bones.

Gomphosis (γόμφος, a nail) is an articulation formed by the insertion of a conical process into a socket, as a nail is driven into a board; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulation of the teeth with the alveoli of the maxillary bones.

Synchondrosis.—Where the connecting medium is cartilage the joint is termed a synchondrosis. This is a temporary form of joint, for the cartilage becomes converted into bone before adult life (synostosis). Such a joint is found between the epiphyses and shafts of long bones.

In this form of articulation the contiguous osseous surfaces are connected together by broad flattened disks of fibro-cartilage, of a more or less complex structure, which adhere to the end of each bone, as in the articulation between the bodies of the vertebrae and the pubic symphyses. This is termed Symphysis. Or, secondly, the bony surfaces are united by an interosseous ligament, as in the inferior tibio-fibular articulation. To this the term Syndesmosis is applied.

This form of articulation includes the greater number of the joints in the body, mobility being their distinguishing character. They are formed by the approximation of two contiguous bony surfaces covered with cartilage, connected by ligaments and lined by synovial membrane. The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial; that is to say, all movements take place around one axis. In one form, the Ginglymus, this axis is, practically speaking, transverse; in the other, the trochoid or pivot-joint, it is longitudinal. There are two varieties where the movement is biaxial, or around two horizontal
axes at right angles to each other or at any intervening axis between the two. These are the condyloid and saddle-joint. There is one form of joint where the movement is polyaxial, the enarthrosis or ball-and-socket joint. And finally there are the Arthrodia or Gliding joints.

**Ginglymus or Hinge-joint (γόνυζως, a hinge).—**In this form of joint the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forward and backward; the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is never in the same plane as that of the axis of the proximal bone, but there is always a certain amount of alteration from the straight line during flexion. The articular surfaces are connected together by strong lateral ligaments, which form their chief bond of union. The most perfect forms of ginglymus are the interphalangeal joints and the joint between the humerus and ulna; the knee and ankle are less perfect, as they allow a slight degree of rotation or lateral movement in certain positions of the limb.

**Trochoides (pivot-joint).—**Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or the ring on the pivot, the ring being formed partly of bone, partly of ligament. In the superior radio-ulnar articulation the ring is formed partly by the lesser sigmoid cavity of the ulna; in the rest of its extent, by the orbicular ligament; here the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas the ring is formed in front by the anterior arch of the atlas; behind, by the transverse ligament; here the ring rotates round the odontoid process.

**Condyloid Articulations.**—In this form of joint an ovoid articular head, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion and extension, adduction and abduction and circumduction, but no axial rotation. The articular surfaces are connected together by anterior, posterior, and lateral ligaments. An example of this form of joint is found in the wrist.

**Articulations by Reciprocal Reception (saddle-joint).—**In this variety the articular surfaces are concavo-convex; that is to say, they are inversely convex in one direction and concave in the other. The movements are the same as in the preceding form; that is to say, there is flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The articular surfaces are connected by a capsular ligament. The best example of this form of joint is the carpo-metacarpal joint of the thumb.

**Enarthrosis** is that form of joint in which the distal bone is capable of motion around an indefinite number of axes which have one common centre. It is formed by the reception of a globular head into a deep cup-like cavity (hence the name "ball-and-socket"), the parts being kept in apposition by a capsular ligament strengthened by accessory ligamentous bands. Examples of this form of articulation are found in the hip and shoulder.

**Arthrodia** is that form of joint which admits of a gliding movement; it is formed by the approximation of plane surfaces or one slightly concave, the other slightly convex, the amount of motion between them being limited by the ligaments, or osseous processes, surrounding the articulation; as in the articular processes of the vertebrae, the carpal joints, except that of the os magnum with the scaphoid and semilunar bones, and the tarsal joints with the exception of the joint between the astragalus and the navicular.

On the next page, in a tabular form, are the names, distinctive characters, and examples of the different kinds of articulations.

### The Kinds of Movement admitted in Joints.

The movements admissible in joints may be divided into four kinds: gliding, angular movement, circumduction, and rotation. These movements are often, however, more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that we find only one kind of motion in any particular joint.
CLASSIFICATION OF JOINTS.

Immovable Joint.

Surfaces separated by fibrous membrane or by line of cartilage, without any intervening synovial cavity, and immovably connected with each other.

As in joints of cranium and face (except lower jaw).

Amphiarthrosis, Mixed Articulation.

As in articulation of rostrum of sphenoid with vomer.

Gomphosis.—Articulation formed by the insertion of a conical process into a socket: the teeth.

Synchondrosis.—Epiphysial lines.

Synphysitis.—Surfaces connected by fibro-cartilage, not separated by synovial membrane, and having limited motion.

As in joints between bodies of vertebra.

Syndesmosis.—Surfaces united by an interosseous ligament.

As in the inferior tibio-fibular articulation.

Ginglymus.—Hinge-joint; motion limited to two directions, forward and backward. Articular surfaces fitted together so as to permit of movement in one plane. As in the interphalangeal joints and the joint between the humerus and the ulna.

Trochoides, or Pivot-joint.—Articulation by a pivot process turning within a ring or ring around a pivot. As in superior radio-ulnar articulation and atlanto-axial joint.

Condyloid.—Ovoid head received into elliptical cavity. Movements in every direction except axial rotation. As the wrist-joint.

Reciproc al Reception (saddle-joint).—Articular surfaces inversely convex in one direction and concave in the other. Movement in every direction except axial rotation. As in the carpo-metacarpal joint of the thumb.

Enarthrosis.—Ball-and-socket joint; capable of motion in all directions. Articulations by a globular head received into a cup-like cavity. As in hip- and shoulder-joints.

Arthrodia.—Gliding joint; articulations by plane surfaces, which glide upon each other. As in carpal and tarsal articulations.
**Gliding movement** is the most simple kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints, but in some, as in the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form, limited by the ligaments which enclose the articulation.

**Angular movement** occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place in four directions: forward and backward, constituting flexion and extension, or inward and outward, from the mesial line of the body (or in the fingers and toes from the middle line of the hand or foot), constituting adduction and abduction. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip, shoulder, and metacarpal joint of the thumb, and partially in the wrist.

**Circumduction** is that limited degree of motion which takes place between the head of a bone and its articular cavity, whilst the extremity and sides of the limb are made to circumscribe a conical space, the base of which corresponds with the inferior extremity of the limb, the apex with the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

**Rotation** is the movement of a bone upon an axis, which is the axis of the pivot on which the bone turns, as in the articulation between the atlas and axis, when the odontoid process serves as a pivot around which the atlas turns; or else is the axis of a pivot-like process which turns within a ring, as in the rotation of the radius upon the humerus.

**Ligamentous Action of Muscles.**—The movements of the different joints of a limb are combined by means of the long muscles which pass over more than one joint, and which, when relaxed and stretched to their greatest extent, act to a certain extent as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other, these latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint be also flexed, so as to bring their attachments nearer together. The uses of this arrangement are threefold: 1. It co-ordinates the kinds of movement which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. “Thus in the usual gesture of the arms, whether in grasping or rejecting, the shoulder and the elbow are flexed simultaneously, and simultaneously extended,” in consequence of the passage of the Biceps and Triceps cubiti over both joints. 2. It enables the short muscles which pass over only one joint to act upon more than one. “Thus, if the Rectus femoris remain tonically of such length that, when stretched over the extended hip, it compels extension of the knee, then the Gluteus maximus becomes not only an extensor of the hip, but an extensor of the knee as well.” 3. It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary. “Taxed beyond its strength, a ligament will be ruptured, whereas a contracted muscle is easily relaxed; also, if neighboring joints be united by ligaments, the amount of flexion or extension of each must remain in constant proportion to that of the other; while, if the union be by muscles, the separation of the points of attachment of those muscles may vary considerably in different varieties of movement, the muscles adapting themselves tonically to the length required.” The quotations are from a very interesting paper by Dr. Cleland in the *Journal of Anatomy and Physiology*, No. 1, 1866, p. 85; by whom I believe this important fact in the mechanism of joints was first clearly pointed out, though it has been independently observed afterward by other anatomists. Dr. W. W. Keen points out how important it is “that the surgeon should remember this ligamentous action of
muscles in making passive motion—for instance, at the wrist after Colles's fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed, as in "making a fist," flexion at the wrist is quickly limited to from forty to fifty degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed." Dr. Keen further points out that "a beautiful illustration of this is seen in the perching of birds, whose toes are forced to clasp the perch by just such a passive ligamentous action so soon as they stoop. Hence they can go to sleep and not fall off the perch."

The articulations may be arranged into those of the trunk, those of the upper extremity, and those of the lower extremity.

**ARTICULATIONS OF THE TRUNK.**

These may be divided into the following groups, viz.:

I. Of the vertebral column.  
II. Of the atlas with the axis.  
III. Of the atlas with the occipital bone.  
IV. Of the axis with the occipital bone.  
V. Of the lower jaw.  
VI. Of the ribs with the vertebrae.

VII. Of the cartilages of the ribs with the sternum and with each other.  
VIII. Of the sternum.  
IX. Of the vertebral column with the pelvis.  
X. Of the pelvis.

**I. Articulations of the Vertebral Column.**

The different segments of the spine are connected together by ligaments, which admit of the same arrangement as the vertebrae. They may be divided into five sets: 1. Those connecting the bodies of the vertebrae. 2. Those connecting the laminae. 3. Those connecting the articular processes. 4. Those connecting the spinous processes. 5. Those of the transverse processes.

The articulations of the bodies of the vertebrae with each other form a series of amphiarthrodial joints (symphyses); those between the articular processes form a series of arthrodial joints.

1. **The Ligaments of the Bodies.**

   **Anterior Common Ligament.**  
   **Posterior Common Ligament.**  
   **Intervertebral Substance.**

The **Anterior Common Ligament** (Figs. 227, 228, 235, 239) is a broad and strong band of ligamentous fibres which extends along the front surface of the bodies of the vertebrae from the axis to the sacrum. It is broader below than above, thicker in the dorsal than in the cervical or lumbar regions, and somewhat thicker opposite the front of the body of each vertebra than opposite the intervertebral substance. It is attached, above, to the body of the axis by a pointed process, where it is continuous with the anterior atlanto-axial ligament, and is connected with the tendon of insertion of the Longus colli muscle, and extends down as far as the upper bone of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral substance and the prominent margins of the vertebrae, but less closely to the middle of the bodies. In the latter situation the fibres are exceedingly thick, and serve to fill up the concavities on their front surface and to make the anterior surface of the spine more even. This ligament is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial or longest fibres extend between four or five vertebrae. A second subjacent set extend between two or three vertebrae, whilst a third set, the shortest and deepest, extend from one vertebra to the next. At the side of the bodies the ligament consists of a few short fibres, which pass from one vertebra to the next, separated from the median portion by large oval apertures for the passage of vessels.

The **Posterior Common Ligament** (Figs. 227, 231) is situated within the spinal
canal, and extends along the posterior surface of the bodies of the vertebrae from the body of the axis above, where it is continuous with the occipito-axial ligament, to the sacrum below. It is broader above than below, and thicker in the dorsal than in the cervical or lumbar regions. In the situation of the intervertebral substance and contiguous margins of the vertebrae, where the ligament is more intimately adherent, it is broad, and presents a series of dentations with intervening concave margins; but it is narrow and thick over the centre of the bodies, from which it is separated by the vena basis vertebrae. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and composed of a superficial layer occupying the interval between three or four vertebrae, and of a deeper layer which extends between one vertebra and the next adjacent to it. It is separated from the dura mater of

the spinal cord by some loose connective tissue which is very liable to serous infiltration.

The Intervertebral Substance (Figs. 227, 236) is a lenticular disk of composite structure interposed between the adjacent surfaces of the bodies of the vertebrae from the axis to the sacrum, and forming the chief bond of connection between those bones. These disks vary in shape, size, and thickness in different parts of the spine. In shape they accurately correspond with the surfaces of the bodies between which they are placed, being oval in the cervical and lumbar regions, and circular in the dorsal. Their size is greatest in the lumbar region. In thickness they vary not only in the different regions of the spine, but in different parts of the same disk: thus, they are much thicker in front than behind in the cervical and lumbar regions, while they are uniformly thick in the dorsal region. The intervertebral disks form about one-fourth of the spinal column, exclusive of the first two vertebrae; they are not equally distributed, however, between the various bones; the dorsal portion of the spine having, in proportion to its length, a much smaller quantity than in the cervical and lumbar regions, which necessarily gives to the latter parts greater pliancy and freedom of movement. The intervertebral disks are adherent, by their surfaces, to a thin layer of hyaline cartilage which covers the upper and under surfaces of the bodies of the vertebrae, and in which the epiphysial plate develops, and by their circumference are closely connected in

![Fig. 227.—Vertical section of two vertebrae and their ligaments, from the lumbar region.](image-url)
front to the anterior, and behind to the posterior common ligament; whilst in the
dorsal region they are connected laterally, by means of the interarticular ligament,
to the heads of those ribs which articulate with two vertebrae; they, consequently,
form part of the articular cavities in which the heads of these bones are received.

Structure of the Intervertebral Substance.—The intervertebral substance is
composed, at its circumference, of laminae of fibrous tissue and fibro-cartilage;
and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish color,
which rises up considerably above the surrounding level when the disk is divided
horizontally. This pulpy substance, which is especially well developed in the
lumbar region, is the remains of the chorda dorsalis, and, according to Luschka,
contains a small synovial cavity in its centre. The laminae are arranged concentrically one within the other, the outermost consisting of ordinary fibrous tissue,
but the others and more numerous consisting of white fibro-cartilage. These
plates are not quite vertical in their direction, those near the circumference being
curved outward and closely approximated; whilst those nearest the centre curve
in the opposite direction, and are somewhat more widely separated. The fibres
of which each plate is composed are directed, for the most part, obliquely from above
downward, the fibres of adjacent plates passing in opposite directions and varying
in every layer; so that the fibres of one layer are directed across those of another,
lke the limbs of the letter X. This laminar arrangement belongs to about the
outer half of each disk. The pulpy substance presents no concentric arrangement,
and consists of a fine fibrous matrix, containing angular cells, united to form a
reticular structure.

2. Ligaments connecting the Laminae.

Ligamenta Subflava.

The Ligamenta Subflava (Fig. 227) are interposed between the laminae of the
vertebrae, from the axis to the sacrum. They are most distinct when seen from
the interior of the spinal canal; when viewed from the outer surface they appear
short, being overlapped by the laminae. Each ligament consists of two lateral
portions, which commence on each side at the root of the articular process, and
pass backward to the point where the laminae converge to form the spinous
process, where their margins are in contact and to a certain extent united; slight
intervals being left for the passage of small vessels. These ligaments consist of
yellow elastic tissue, the fibres of which, almost perpendicular in direction, are
attached to the anterior surface of the laminae above, some distance from its
inferior margin, and to the posterior surface, as well as to the margin of the
lamina below. In the cervical region they are thin in texture, but very broad and
long; they become thicker in the dorsal region, and in the lumbar acquire very
considerable thickness. Their highly elastic property serves to preserve the
upright posture and to assist in resuming it after the spine has been flexed.
These ligaments do not exist between the occiput and atlas or between the atlas
and axis.

3. Ligaments connecting the Articular Processes.

Capsular.

The Capsular Ligaments (Fig. 229) are thin and loose ligamentous sacs, attached
to the contiguous margins of the articulating processes of each vertebra through
the greater part of their circumference, and completed internally by the ligamenta
subflava. They are longer and looser in the cervical than in the dorsal or lumbar
regions. The capsular ligaments are lined on their inner surface by synovial
membrane.

4. Ligaments connecting the Spinous Processes.

Supraspinous.

Interspinous.

The Supraspinous Ligament (Fig. 227) is a strong fibrous cord, which connects
together the apices of the spinous processes from the seventh cervical to the spinous processes of the sacrum. It is thicker and broader in the lumbar than in the dorsal region, and intimately blended, in both situations, with the neighboring aponeurosis. The most superficial fibres of this ligament connect three or four vertebrae; those deeper-seated pass between two or three vertebrae; whilst the deepest connect the contiguous extremities of neighboring vertebrae. It is continued upward to the external occipital protuberance, as the posterior margin of the ligamentum nuchæ, which, in the human subject, is comparatively thin and forms an intermuscular septum.

The **Interspinous Ligaments** (Fig. 227), thin and membranous, are interposed between the spinous processes. Each ligament extends from the root to the summit of each spinous process and connects together their adjacent margins. They are narrow and elongated in the dorsal region; broader, quadrilateral in form, and thicker in the lumbar region; and only slightly developed in the neck.

5. **Ligaments connecting the Transverse Processes.**

**Intertransverse.**

The **Intertransverse Ligaments** consist of bundles of fibres interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the dorsal, they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

**Actions.**—The movements permitted in the spinal column are, Flexion, Extension, Lateral Movement, Circumduction, and Rotation.

In **Flexion**, or movement of the spine forward, the anterior common ligament is relaxed, and the intervertebral substances are compressed in front, while the posterior common ligament, the ligamenta subflava, and the inter- and supraspinous ligaments are stretched, as well as the posterior fibres of the intervertebral disks. The interspaces between the laminae are widened, and the inferior articular processes of the vertebrae above glide upward upon the articular processes of the vertebrae below. Flexion is the most extensive of all the movements of the spine.

In **Extension**, or movement of the spine backward, an exactly opposite disposition of the parts takes place. This movement is not extensive, being limited by the anterior common ligament and by the approximation of the spinous processes.

Flexion and extension are most free in the lower part of the lumbar region between the third and fourth and fourth and fifth lumbar vertebrae; above the third they are much diminished, and reach their minimum in the middle and upper part of the back. They increase again in the neck, the capability of motion backward from the upright position being in this region greater than that of the motion forward, whereas in the lumbar region the reverse is the case.

In **Lateral Movement**, the sides of the intervertebral disks are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments and by the approximation of the transverse processes. This movement may take place in any part of the spine, but is most free in the neck and loins.

**Circumduction** is very limited, and is produced merely by a succession of the preceding movements.

**Rotation** is produced by the twisting of the intervertebral substances; this, although only slight between any two vertebrae, produces a great extent of movement when it takes place in the whole length of the spine, the front of the column being turned to one or the other side. This movement takes place only to a slight extent in the neck, but is freer in the upper part of the dorsal region, and is altogether absent in the lumbar region.

It is thus seen that the **cervical region** enjoys the greatest extent of each variety of movement, flexion and extension especially being very free. In the **dorsal region** the three movements of flexion, extension, and circumduction are only permitted to a slight extent, while rotation is very free in the upper part and
ceases below. In the lumbar region there is free flexion, extension, and lateral movement, but no rotation.

As Sir George Humphry has pointed out, the movements permitted are mainly due to the shape and position of the articulating processes. In the loins the inferior articulating processes are turned outward and embraced by the superior; this renders rotation in this region of the spine impossible, while there is nothing to prevent a sliding upward and downward of the surfaces on each other, so as to allow of flexion and extension. In the dorsal region, on the other hand, the articulating processes, by their direction and mutual adaptation, especially at the upper part of the series, permit of rotation, but prevent extension and flexion, while in the cervical region the greater obliquity and lateral slant of the articular processes allow not only flexion and extension, but also rotation.

The principal muscles which produce flexion are the Sterno-mastoid, Rectus capitis anticus major, and Longus colli; the Scaleni; the abdominal muscles and the Psoas magnus. Extension is produced by the fourth layer of the muscles of the back, assisted in the neck by the Splenius, Semispinalis dorsi et colli, and the Multifidus spinæ. Lateral motion is produced by the fourth layer of the muscles of the back, by the Splenius and the Scaleni, the muscles of one side only acting; and rotation by the action of the following muscles of one side only—viz. the Sterno-mastoid, the Rectus capitis anticus major, the Scaleni, the Multifidus spinæ, the Complexus, and the abdominal muscles.

II. Articulation of the Atlas with the Axis.

The articulation of the Atlas with the Axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between the odontoid process of the axis and the ring formed between the anterior arch of the atlas and the transverse ligament (see Fig. 230). Here there are two joints: one in front between the posterior surface of the anterior arch of the atlas and the front of the odontoid process (the atlanto-odontoid joint of Cruevillier); the other between the anterior surface of the transverse ligament and the back of the process (the syndesmo-odontoid joint). Between the articular processes of the two bones there is a double arthrodiia or gliding joint. The ligaments which connect these bones are the

Two Anterior Atlanto-axial.
Posterior Atlanto-axial.

Transverse.
Two Capsular.

Of the Two Anterior Atlanto-axial Ligaments (Fig. 228), the more superficial is a rounded cord, situated in the middle line; it is attached, above, to the tubercle on the anterior arch of the atlas; below, to the base of the odontoid process and to the front of the body of the axis. The deeper ligament is a membranous layer, attached, above, to the lower border of the anterior arch of the atlas; below, to the base of the odontoid process and front of the body of the axis. These ligaments are in relation, in front, with the Recti antici majores.

The Posterior Atlanto-axial Ligament (Fig. 229) is a broad and thin membranous layer, attached, above, to the lower border of the posterior arch of the atlas; below, to the upper edge of the laminae of the axis. This ligament supplies the place of the ligamenta subflava, and is in relation, behind, with the Inferior oblique muscles.

The Transverse Ligament1 (Figs. 230, 231) is a thick and strong ligamentous band, which arches across the ring of the atlas, and serves to retain the odontoid process in firm connection with its anterior arch. This ligament is flattened from before backward, broader and thicker in the middle than at either extremity, and

1 It has been found necessary to describe the transverse ligament with those of the atlas and axis; but the student must remember that it is really a portion of the mechanism by which the movements of the head on the spine are regulated; so that the connections between the atlas and axis ought always to be studied together with those between the latter bones and the skull.
firmly attached on each side to a small tubercle on the inner surface of the lateral mass of the atlas. As it crosses the odontoid process, a small fasciculus is derived from its upper and lower borders; the former passing upward, to be inserted into the basilar process of the occipital bone; the latter, downward, to be attached to the posterior surface of the body of the axis; hence, the whole ligament has received the name of cruciform. The transverse ligament divides the ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the cord and its membranes and the spinal accessory nerves; the anterior and smaller contains the odontoid process. Since the space between the anterior arch of the atlas and the transverse ligament is smaller at the lower part than the upper (because the transverse ligament embraces firmly the narrow neck of the odontoid process), this process is retained in firm connection with the atlas after all the other ligaments have been divided.

The Capsular Ligaments connect the articular processes of the atlas and axis, the fibres being strongest on the posterior and internal part of the articulation, accessory ligaments; these latter extend downward and inward to the body of the axis.

There are four Synovial Membranes in this articulation: one lining the inner surface of each of the capsular ligaments; one between the anterior surface of the odontoid process and the anterior arch of the atlas, the atlanto-odontoid joint; and one between the posterior surface of the odontoid process and the transverse ligament, the syndesmo-odontoid joint. The latter often communicates with those between the condyles of the occipital bone and the articular surfaces of the atlas.

Actions.—This joint allows the rotation of the atlas (and, with it, of the cranium) upon the axis, the extent of rotation being limited by the odontoid ligaments.

The principal muscles by which this action is produced are the Sterno-mastoid and Complexus of one side, acting with the Rectus capitis anticus major, Splenius, Trachelo-mastoid, Rectus capitis posticus major, and Inferior oblique of the other side.
OF THE ATLAS WITH THE OCCIPITAL BONE.

ARTICULATIONS OF THE SPINE WITH THE CRANIUM.

The ligaments connecting the spine with the cranium may be divided into two sets—those connecting the occipital bone with the atlas, and those connecting the occipital bone with the axis.

III. Articulation of the Atlas with the Occipital Bone.

This articulation is a double condyloid joint. Its ligaments are the

- Two Anterior Occipito-atlantal.
- Posterior Occipito-atlantal.
- Two Lateral Occipito-atlantal.
- Two Capsular.

Of the Two Anterior Occipito-atlantal Ligaments (Fig. 228), the superficial is a strong, narrow, rounded cord, attached, above, to the basilar process of the occiput; below, to the tubercle on the anterior arch of the atlas: the deeper ligament is a broad and thin membranous layer which passes between the anterior margin of the foramen magnum above, and the whole length of the upper border of the anterior arch of the atlas below. This ligament is in relation, in front, with the Recti antici minores; behind, with the odontoid ligaments.

The Posterior Occipito-atlantal Ligament (Fig. 229) is a very broad but thin membranous lamina intimately blended with the dura mater. It is connected, above, to the posterior margin of the foramen magnum; below, to the upper border of the posterior arch of the atlas. This ligament is incomplete at each side, and forms, with the superior intervertebral notch, an opening for the passage of the vertebral artery and suboccipital nerve. It is in relation, behind, with the Recti postici minores and Obliqui superiores; in front, with the dura mater of the spinal canal, to which it is intimately adherent.

The Lateral Ligaments are strong fibrous bands, directed obliquely upward and inward, attached above to the jugular process of the occipital bone; below, to the base of the transverse process of the atlas.

The Capsular Ligaments surround the condyles of the occipital bone, and con-
nect them with the articular processes of the atlas; they consist of thin and loose capsules, which enclose the synovial membrane of the articulation.

**Synovial Membranes.**—There are two synovial membranes in this articulation, one lining the inner surface of each of the capsular ligaments. These occasionally communicate with that between the posterior surface of the odontoid process and the transverse ligament.

**Actions.**—The movements permitted in this joint are flexion and extension, which give rise to the ordinary forward and backward nodding of the head, besides slight lateral motion to one or the other side. When either of these actions is carried beyond a slight extent, the whole of the cervical portion of the spine assists in its production. Flexion is mainly produced by the action of the Rectus capitis anticus major et minor and the Sterno-mastoid muscles; extension by the Rectus capitis posticus major et minor, the Superior oblique, the Complexus, Splenius, and upper fibres of the Trapezius. The Recti laterales are concerned in the lateral movement, assisted by the Trapezius, Splenius, Complexus, Sterno-mastoid, and the Recti laterales of the same side, all acting together. According to Cruveilhier, there is a slight motion of rotation in this joint.

**IV. Articulation of the Axis with the Occipital Bone.**

**Occipito-axial.**

Three Odontoid.

To expose these ligaments the spinal canal should be laid open by removing the posterior arch of the atlas, the laminae and spinous process of the axis, and the portion of the occipital bone behind the foramen magnum, as seen in Fig. 231.

The **Occipito-axial Ligament** (apparatus ligamentosus colli) is situated within the spinal canal. It is a broad and strong ligamentous band, which covers the odontoid process and its ligaments, and appears to be a prolongation upward of the posterior common ligament of the spine. It is attached, below, to the posterior surface of the body of the axis, and, becoming expanded as it ascends, is inserted into the basilar groove of the occipital bone, in front of the foramen magnum, where it becomes blended with the dura mater of the skull.

**Relations.**—By its anterior surface with the transverse ligament, by its posterior surface with the dura mater.

The **Lateral Odontoid** or **Check Ligaments** (alar ligaments) are strong, fibrous cords, which arise on either side of the upper part of the odontoid process, and, passing obliquely upward and outward, are inserted into the rough depressions on the inner side of the condyles of the occipital bone. In the triangular interval between these ligaments another strong fibrous cord (ligamentum suspensorium or middle odontoid ligament) may be seen, which passes almost perpendicularly from the apex of the odontoid process to the anterior margin of the foramen, being intimately blended with the deep portion of the
anterior occipito-atloid ligament and upper fasciculus of the transverse ligament of the atlas.

**Actions.**—The odontoid ligaments serve to limit the extent to which rotation of the cranium may be carried; hence they have received the name of check ligaments.

In addition to these ligaments, which connect the atlas and axis to the skull, the ligamentum nuchae must be regarded as one of the ligaments by which the spine is connected with the cranium. It is described on a subsequent page.

**Surgical Anatomy.**—The ligaments which unite the component parts of the vertebrae together are so strong, and these bones are so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, indeed, unless accompanied by fracture, rarely occurs. Except in the upper part of the neck. Dislocation of the occiput from the atlas has only been recorded in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common; it is the mode in which death is produced in many cases of execution by hanging. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.

**V. Temporo-maxillary Articulation.**

This is a double or bilateral condyloid joint: the parts entering into its formation on each side are, above, the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis; and, below, the condyle of the lower jaw. The ligaments are the following:

- **External Lateral.**
- **Stylo-maxillary.**
- **Internal Lateral.**
- **Capsular.**
- **Interarticular Fibro-cartilage.**

The **External Lateral Ligament** (Fig. 232) is a short, thin, and narrow fasciculus, attached, above, to the outer surface of the zygoma and to the rough tubercle on its lower border; below, to the outer surface and posterior border of the neck of the lower jaw. It is broader above than below; its fibres are placed
parallel with one another, and directed obliquely downward and backward. Externally, it is covered by the parotid gland and by the integument. Internally, it is in relation with the capsular ligament, of which it is an accessory band, and not separable from it.

The **Internal Lateral Ligament** (Fig. 233) is a specialized band of cervical fascia which is attached above to the spinous process of the sphenoid bone, and, becoming broader as it descends, is inserted into the lingula and margin of the dental foramen. Its outer surface is in relation, above, with the External pterygoid muscle; lower down, it is separated from the neck of the condyle by the internal maxillary artery; and still more inferiorly, the inferior dental vessels and nerve separate it from the ramus of the jaw. The inner surface is in relation with the Internal pterygoid.

The **Stylo-maxillary Ligament** is also a specialized band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the lower jaw, between the Masseter and Internal pterygoid muscles. This ligament separates the parotid from the submaxillary gland, and has attached to its inner side part of the fibres of origin of the Stylo-glossus muscle. Although usually classed among the ligaments of the jaw, it can only be considered as an accessory in the articulation.
The **Capsular Ligament** forms a thin and loose ligamentous capsule, attached above to the circumference of the glenoid cavity and the articular surface immediately in front; below, to the neck of the condyle of the lower jaw. It consists of a few thin scattered fibres, and can hardly be considered as a distinct ligament; it is thickest at the back part of the articulation.\(^1\)

The **Interarticular Fibro-cartilage** (Fig. 234) is a thin plate of an oval form, placed horizontally between the condyle of the jaw and the glenoid cavity. Its upper surface is concavo-convex from before backward, and a little convex transversely, to accommodate itself to the form of the glenoid cavity. Its under surface, where it is in contact with the condyle, is concave. Its circumference is connected to the capsular ligament, and in front to the tendon of the External pterygoid muscle. It is thicker at its circumference, especially behind, than at its centre, where, at times, it is perforated. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre. Its surfaces are smooth. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

The **Synovial Membranes**, two in number, are placed, one above, and the other below, the fibro-cartilage. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the glenoid cavity and eminentia articularis on to the upper surface of the fibro-cartilage. The lower one passes from the under surface of the fibro-cartilage to the neck of the condyle of the jaw, being prolonged downward a little farther behind than in front.

The **nerves** of this joint are derived from the auriculo-temporal and masseteric branches of the inferior maxillary. The **arteries** are derived from the temporal branch of the external carotid.

**Actions.**—The movements permitted in this articulation are very extensive. Thus, the jaw may be depressed or elevated, or it may be carried forward or backward or from side to side. It is by the alternation of these movements, performed in succession, that a kind of rotatory motion of the lower jaw upon the upper takes place, which materially assists in the mastication of the food.

If the movement of depression is carried only to a slight extent, the condyles remain in the glenoid cavities, rotating on a transverse axis against the interarticular fibro-cartilage; but if the depression is considerable, the condyles slide from the glenoid fossa on to the articular eminences, carrying with them the interarticular fibro-cartilages, so that in opening the mouth widely the two movements are combined—i.e., the condyle rotates on a transverse axis against the fibro-cartilage, and at the same time glides forward, carrying the fibro-cartilage with it. When the jaw is elevated after forced depression, the condyles and fibro-cartilages return to their original position. When the jaw is carried forward and backward or from side to side, an oblique gliding movement of the fibro-cartilages and condyles upon the glenoid cavities takes place in the corresponding direction.

The lower jaw is **depressed** by its own weight, assisted by the Platysma, the Digastric, the Mylo-hyoid, and the Genio-hyoid. It is **elevated** by the anterior part of the Temporal, Masseter, and Internal pterygoid. It is drawn **forward** by

---

\(^1\) Sir G. Humphry describes the internal portion of the capsular ligament separately, as the short internal lateral ligament; and it certainly seems as deserving of a separate description as the external lateral ligament is.
the simultaneous action of the External pterygoid and the superficial fibres of the Masseter; and it is drawn backward by the deep fibres of the Masseter and the posterior fibres of the Temporal muscle. The grinding movement is caused by the alternate action of the two External pterygoids.

**Surface Form.**—The temporo-maxillary articulation is quite superficial, situated below the base of the zygoma, in front of the tragus and external auditory meatus, and behind the posterior border of the upper part of the Masseter muscle. Its exact position can be at once ascertained by feeling for the condyle of the jaw, the working of which can be distinctly felt in the movements of the lower jaw either vertically or from side to side. When the mouth is opened wide, the condyle advances out of the glenoid fossa on to the eminentia articularis and a depression is felt in the situation of the joint.

**Surgical Anatomy.**—The lower jaw is dislocated only in one direction—viz. forward. The accident is caused by violence or muscular action. When the mouth is open, the condyle is situated on the eminentia articularis, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forward into the zygomatic fossa. The displacement may be unilateral or bilateral, according as one or both of the condyles are displaced. The latter of the two is the more common.

Sir Astley Cooper described a condition which he termed "subluxation." It occurs principally in delicate women, and is believed by some to be due to the relaxation of the ligaments, permitting too free movement of the bone, and possibly some displacement of the fibrocartilage. Others have believed that it is due to gouty or rheumatic changes in the joint. In close relation to the condyle of the jaw is the external auditory meatus and the tympanum; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation of the joint may extend to the ear, or on the other hand inflammation of the middle ear may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. In children, arthritis of this joint may also follow the exanthema, and in adults occurs as the result of some constitutional conditions, as rheumatism or gout. The temporo-maxillary joint is also frequently the seat of osteo-arthritis, leading to great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the lower jaw, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

**VI. Articulations of the Ribs with the Vertebrae.**

The articulations of the ribs with the vertebral column may be divided into two sets: 1. Those which connect the heads of the ribs with the bodies of the vertebrae, costa-central. 2. Those which connect the necks and tubercles of the ribs with the transverse processes, costa-transverse.

1. **Articulations between the Heads of the Ribs and the Bodies of the Vertebrae** (Fig. 235).

These constitute a series of arthrodial joints, formed by the articulation of the heads of the ribs with the cavities on the contiguous margins of the bodies of the dorsal vertebrae, connected together by the following ligaments:

- **Anterior Costo-central or Stellate.**
- **Capsular.**
- **Interarticular.**

The **Anterior Costa-vertebral or Stellate Ligament** connects the anterior part of the head of each rib with the sides of the bodies of two vertebrae and the intervertebral disk between them. It consists of three flat bundles of ligamentous fibres, which radiate from the anterior part of the head of the rib. The superior fasciculus passes upward to be connected with the body of the vertebra above; the inferior one descends to the body of the vertebra below; and the middle one, the smallest and least distinct, passes horizontally inward, to be attached to the intervertebral substance.

**Relations.**—In front, with the thoracic ganglia of the sympathetic, the pleura, and, on the right side, with the vena azygos major; behind, with the interarticular ligament and synovial membranes.

In the first rib, which articulates with a single vertebra only, this ligament does not present a distinct division into three fasciculi; its fibres, however, radiate, and are attached to the body of the last cervical vertebra, as well as to the body of the vertebra with which the rib articulates. In the tenth, eleventh, and twelfth ribs also, which likewise articulate with a single vertebra, the division does not
exist; but the fibres of the ligament in each case radiate and are connected with the vertebra above, as well as that with which the ribs articulate.

The Capsular Ligament is a thin and loose ligamentous bag, which surrounds the joint between the head of the rib and the articular cavity formed by the intervertebral disk and the adjacent vertebra. It is very thin, firmly connected with the anterior ligament, and most distinct at the upper and lower parts of the articulation. Behind, some of its fibres pass through the intervertebral foramen to the back of the intervertebral disk. This is the analogue of the ligamentum conjunctivum of some mammals, which unites the heads of opposite ribs across the back of the intervertebral disk.

The Interarticular Ligament is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downward, attached by one extremity to the sharp crest on the head of the rib, and by the other to the intervertebral disk. It divides the joint into two cavities, which have no communication with each other. In the first, tenth, eleventh, and twelfth ribs the interarticular ligament does not exist; consequently, there is but one synovial membrane.

The Synovial Membrane.—There are two synovial membranes in each of the articulations in which there is an interarticular ligament, one on each side of this structure.

2. Articulations of the Necks and Tubercles of the Ribs with the Transverse Processes (Fig. 236).

The articular portion of the tubercle of the rib and adjacent transverse process form an arthrodial joint.

In the eleventh and twelfth ribs this articulation is wanting.

The ligaments connecting these parts are the—

Superior Costo-transverse.
Middle Costo-transverse (Interosseous).
Posterior Costo-transverse.
Capsular.

The Superior Costo-transverse Ligament has two sets of fibres: the one (anterior costo-transverse ligament) is attached to the crest of the upper border of the neck of each rib, and passes obliquely upward and outward to the lower border of the transverse process immediately above; the other (posterior costo-transverse ligament) is attached to the neck of the rib, and passes upward and inward to the base of the transverse process and border of the lower articular process of the vertebra above. This ligament is in relation, in front, with the intercostal vessels and nerves; behind, with the Longissimus dorsi. Its internal border completes an aperture formed between it and the articular processes, through which pass the
posterior branches of the intercostal vessels and nerves. Its external border is continuous with a thin aponeurosis which covers the External intercostal muscle.

The first rib has no anterior costo-transverse ligament.

The Middle Costo-transverse or Interosseous Ligament consists of short but strong fibres which pass between the rough surface on the posterior part of the neck of each rib and the anterior surface of the adjacent transverse process. In order fully to expose this ligament, a horizontal section should be made across the transverse process and corresponding part of the rib; or the rib may be forcibly separated from the transverse process and its fibres put on the stretch.

In the eleventh and twelfth ribs this ligament is quite rudimentary or wanting.

The Posterior Costo-transverse Ligament is a short but thick and strong fasciculus which passes obliquely from the summit of the transverse process to the rough non-articular portion of the tubercle of the rib. This ligament is shorter and more oblique in the upper than in the lower ribs. Those corresponding to the superior ribs ascend, while those of the inferior ribs descend slightly.

In the eleventh and twelfth ribs this ligament is wanting.

The Capsular Ligament is a thin, membranous sac attached to the circumference of the articular surfaces, and enclosing a small synovial membrane.

In the eleventh and twelfth ribs this ligament is absent.

Actions.—The heads, necks, and tubercles of the ribs are so closely connected to the bodies and transverse processes of the vertebrae that only a slight gliding movement of the articular surfaces on each other can take place in these articulations. The result of this gliding movement is for the upper six ribs an elevation of the front and middle portion of the rib, the hinder part being prevented from performing any upward movement by its close connection with the spine. In this gliding movement the rib rotates on an axis corresponding with a line drawn through the two articulations, Costa-central and Costa-transverse, which the rib forms with the spine. Of the four succeeding ribs, each one, besides rotating on the above-mentioned axis, also rotates on an axis corresponding with a line drawn from the head of the rib to the sternum. In other words, an upward and backward gliding is permitted between tubercle and transverse process, owing to the especial degree of obliquity existing between the corre-

![Fig. 236.—Costo-transverse articulation. Seen from above.](image-url)
sponding facets. By the first movement an elevation of the anterior part of the rib takes place, and a consequent enlargement of the antero-posterior diameter of the chest. None of the ribs lie in a truly horizontal plane; they are all directed more or less obliquely, so that their anterior extremities lie on a lower level than their posterior, and this obliquity increases from the first to the seventh, and then again decreases. If we examine any one rib—say, that in which there is the greatest obliquity—we shall see that it is obvious that as its sternal extremity is carried upward, it must also be thrown forward; so that the rib may be regarded as a radius moving on the vertebral joint as a centre, and causing the sternal attachment to describe an arc of a circle in the vertical plane of the body. Since all the ribs are oblique and connected in front to the sternum by the elastic costal cartilages, they must have a tendency to thrust the sternum forward, and so increase the antero-posterior diameter of the chest. By the second movement—that of the rotation of the rib on an axis corresponding with a line drawn from the head of the rib to the sternum—an elevation of the middle portion of the rib takes place, and consequently an increase in the transverse diameter of the chest. This elevation of the 3d, 4th, 5th, and 6th ribs is due entirely to the shapes of the ribs—i. e. each rib being bent or twisted around three axes—and not to this movement (see above). For the 7th, 8th, 9th, and 10th ribs this elevation is due both to their shapes and to this movement. The last two ribs move chiefly backward and forward, and with very little "elevation" of their middle portions (see Fig. 237). The mobility of the different ribs varies very much. The first rib is more fixed than the others, on account of the weight of the upper extremity and the strain of the ribs beneath; but on the freshly dissected thorax it moves as freely as the others. From the same causes the movement of the second rib is also not very extensive. In the other ribs this mobility increases successively down to the last two, which are very movable. The ribs are generally more movable in the female than in the male.

VII. Articulation of the Cartilages of the Ribs with the Sternum, etc. (Fig. 238).

The articulations of the cartilages of the true ribs with the sternum are arthrodiyal joints, with the exception of the first, in which the cartilage is almost always directly united with the sternum, and which must therefore be regarded as a synarthrodial articulation. The ligaments connecting them are—
The Anterior Chondro-sternal Ligament is a broad and thin membranous band that radiates from the front of the inner extremity of the cartilages of the true ribs to the anterior surface of the sternum. It is composed of fasciculi which pass in different directions. The superior fasciculi ascend obliquely, the inferior pass obliquely downward, and the middle fasciculi horizontally. The superficial fibres of this ligament are the longest: they intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane which covers the surface of the sternum. This is more distinct at the lower than at the upper part.

The Posterior Chondro-sternal Ligament, less thick and distinct than the anterior, is composed of fibres which radiate from the posterior surface of the sternal end of the cartilages of the true ribs to the posterior surface of the sternum, becoming blended with the periosteum.

The Capsular Ligament surrounds the joints formed between the cartilages of the true ribs and the sternum. It is very thin, intimately blended with the anterior and posterior ligaments, and strengthened at the upper and lower part of the articulation by a few fibres which pass from the cartilage to the side of the sternum. These ligaments protect the synovial membranes.

The Interarticular Chondro-sternal Ligaments.—These are only found between the second and third costal cartilages and the sternum. The cartilage of the second rib is connected with the sternum by means of an interarticular ligament attached by one extremity to the cartilage of the second rib, and by the other extremity to the cartilage which unites the first and second pieces of the sternum. This articulation is provided with two synovial membranes. The cartilage of the third rib is connected with the sternum by means of an interarticular ligament which is attached by one extremity to the cartilage of the third rib, and by the other extremity to the point of junction of the second and third pieces of the sternum. This articulation is provided with two synovial membranes.

The Anterior Chondro-xiphoide.—This is a band of ligamentous fibres which connects the anterior surface of the seventh costal cartilage, and occasionally also that of the sixth, to the anterior surface of the ensiform appendix. It varies in length and breadth in different subjects.

The Posterior Chondro-xiphoide is a similar band of fibres on the internal or posterior surface, though less thick and distinct.

Synovial Membranes.—There is no synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the sternum. There are two synovial membranes, both in the articulation of the second and third costal cartilages to the sternum. There is generally one synovial membrane in each of the joints between the fourth, fifth, sixth, and seventh costal cartilages to the sternum; but it is sometimes absent in the sixth and seventh chondro-sternal joints. Thus there are eight synovial cavities on each side in the articulations between the costal cartilages of the true ribs and the sternum. After middle life the articular surfaces lose their polish, become roughened, and the synovial membranes appear to be wanting. In old age the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum.

Actions.—The movements which are permitted in the chondro-sternal articulations are limited to elevation and depression, and these only to a slight extent.

Articulations of the Cartilages of the Ribs with each other (Interchondral) (Fig. 238).

The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small, smooth,
of the ribs with their cartilages.

Oblong-shaped facets. Each articulation is enclosed in a thin capsular ligament lined by synovial membrane, and strengthened externally and internally by ligamentous fibres (interchondral ligaments) which pass from one cartilage to the other. Sometimes the fifth costal cartilage, more rarely that of the ninth, articulates, by its lower border, with the adjoining cartilage by a small oval facet; more

The synovial cavities exposed by a vertical section of the sternum and cartilages.

frequently they are connected together by a few ligamentous fibres. Occasionally the articular surfaces above mentioned are wanting.

Articulations of the Ribs with their Cartilages (Costo-chondral)
(Fig. 238).

The outer extremity of each costal cartilage is received into a depression in the sternal end of the ribs, and the two are held together by the periosteum.
VIII. Ligaments of the Sternum.

The first piece of the sternum is united to the second either by an amphiarthrodial joint—a single piece of true fibro-cartilage uniting the segments—or by a diarthrodial joint, in which each bone is clothed with a distinct lamina of cartilage, adherent on one side, free and lined with synovial membrane on the other. In the latter case the cartilage covering the gladiolus is continued without interruption on to the cartilages of the second ribs. Mr. Rivington has found the diarthrodial form of joint in about one-third of the specimens examined by him; Mr. Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Mr. Rivington’s opinion, from the amphiarthrodial form by absorption. The diarthrodial joint seems to have no tendency to ossify at any age, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. The two segments are further connected by an

Anterior Intersternal Ligament and a
Posterior Intersternal Ligament.

The Anterior Intersternal Ligament consists of a layer of fibres, having a longitudinal direction; it blends with the fibres of the anterior chondro-ternal ligaments on both sides, and with the tendinous fibres of origin of the Pectoralis major. This ligament is rough, irregular, and much thicker below than above.

The Posterior Intersternal Ligament is disposed in a somewhat similar manner on the posterior surface of the articulation.

IX. Articulation of the Pelvis with the Spine.

The ligaments connecting the last lumbar vertebra with the sacrum are similar to those which connect the segments of the spine with each other—viz.: 1. The continuation downward of the anterior and posterior common ligaments. 2. The intervertebral substance connecting the flattened oval surfaces of the two bones and forming an amphiarthrodial joint. 3. Ligamenta subflava, connecting the arch of the last lumbar vertebra with the posterior border of the sacral canal. 4. Capsular ligaments connecting the articulating processes and forming a double arthrodia. 5. Inter- and supraspinous ligaments.

The two proper ligaments connecting the pelvis with the spine are the lumbo-sacral and ilio-lumbar.

The Lumbo-sacral Ligament (Fig. 239) is a short, thick, triangular fascieulus, which is connected above to the lower and front part of the transverse process of the last lumbar vertebra, passes obliquely outward, and is attached below to the lateral surface of the base of the sacrum, becoming blended with the anterior sacro-iliac ligament. This ligament is in relation, in front, with the Psoas muscle, and represents the anterior costo-transverse ligament.

The Ilio-lumbar Ligament (Fig. 239) passes horizontally outward from the apex of the transverse process of the last lumbar vertebra to the crest of the ilium immediately in front of the sacro-iliac articulation. It is of a triangular form, thick and narrow internally, broad and thinner externally. It is in relation, in front, with the Psoas muscle; behind, with the muscles occupying the vertebral groove; above, with the Quadratus lumbrorum.

X. Articulations of the Pelvis.

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: 1. Those connecting the sacrum and ilium. 2. Those passing between the sacrum and ischium. 3. Those connecting the sacrum and coccyx. 4. Those between the two pubic bones.

1. Articulations of the Sacrum and Ilium.

The sacro-iliac articulation is formed between the lateral surfaces of the sacrum and ilium. The anterior or auricular portion of each articular surface
is covered with a thin plate of cartilage, thicker on the sacrum than on the ilium. The surfaces of these cartilages are usually in close contact, but not united. Sometimes fine fibres are found running between portions of these surfaces, which in other cases may be, in the adult, rough and irregular, and separated from one another by spaces containing synovial-like fluid. The ligaments connecting these surfaces are the anterior and posterior sacro-iliac.

The **Anterior Sacro-iliac Ligament** (Fig. 239) consists of numerous thin ligamentous bands which connect the anterior surfaces of the sacrum and ilium.

![Articulations of pelvis and hip. Anterior view.](image)

The **Posterior Sacro-iliac** (Fig. 240) is a strong interosseous ligament, situated in a deep depression between the sacrum and ilium behind, and forming the chief bond of connection between those bones. It consists of numerous strong fasciculi which pass between the bones in various directions. Three of these are of large size: the *two superior*, nearly horizontal in direction, arise from the first and second transverse tubercles on the posterior surface of the sacrum, and are inserted into the rough, uneven surface at the posterior part of the inner surface of the ilium. The third fasciculus, oblique in direction, is attached by one extremity to the third transverse tubercle on the posterior surface of the sacrum, and by the other to the posterior superior spine of the ilium; it is sometimes called the *oblique sacro-iliac ligament*.

The position of the sacro-iliac joint is indicated by the posterior superior spine of the ilium. This process is immediately behind the centre of the articulation.

2. **Ligaments passing between the Sacrum and Ischium** (Fig. 240).

   The Great Sacro-sciatic (Posterior).
   The Lesser Sacro-sciatic (Anterior).

   The **Great or Posterior Sacro-sciatic Ligament** is situated at the lower and back part of the pelvis. It is thin, flat, and triangular in form; narrower in the
middle than at the extremities; attached by its broad base to the posterior inferior spine of the ilium, to the fourth and fifth transverse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downward, outward, and forward, it becomes narrow and thick, and at its insertion into the inner margin of the tuberosity of the ischium it increases in breadth, and is prolonged forward along the inner margin of the ramus, forming what is known as the falciform ligament. The free concave edge of this prolongation has attached to it the obturator fascia, with which it forms a kind of groove, protecting the internal pudic vessels and nerve. One of its surfaces is turned toward the perineum, the other toward the Obturator internus muscle.

The posterior surface of this ligament gives origin, by its whole extent, to fibres of the Gluteus maximus. Its anterior surface is united to the lesser sacro-sciatic ligament. Its external border forms, above, the posterior boundary of the great sacro-sciatic foramen, and, below, the lower boundary of the lesser sacro-sciatic foramen. Its lower border forms part of the boundary of the perineum. It is pierced by the coccygeal branch of the sciatic artery and coccygeal nerve.

The Lesser or Anterior Sacro-sciatic Ligament, much shorter and smaller than the preceding, is thin, triangular in form, attached by its apex to the spine of the ischium, and internally, by its broad base, to the lateral margin of the sacrum and coccyx, anterior to the attachment of the great sacro-sciatic ligament, with which its fibres are intermingled.

It is in relation, anteriorly, with the Coccygeus muscle; posteriorly, it is covered by the great sacro-sciatic ligament and crossed by the internal pudic vessels and nerve. Its superior border forms the lower boundary of the great sacro-sciatic foramen; its inferior border, part of the lesser sacro-sciatic foramen.

These two ligaments convert the sacro-sciatic notches into foramina. The superior or great sacro-sciatic foramen is bounded, in front and above, by the
posterior border of the os innominatum; behind, by the great sacro-sciatic ligament; and below, by the lesser sacro-sciatic ligament. It is partially filled up, in the recent state, by the Pyriformis muscle, which passes through it. Above this muscle the gluteal vessels and superior gluteal nerve emerge from the pelvis, and, below it, the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus. The *inferior* or *lesser* sacro-sciatic foramen is bounded, in front, by the *tuber ischii*; above, by the spine and lesser sacro-sciatic ligament; behind, by the greater sacro-sciatic ligament. It transmits the tendon of the Obturator internus muscle, its nerve, and the internal pudic vessels and nerve.

3. **Articulation of the Sacrum and Coccyx.**

This articulation is an arthrodial joint, and is formed between the oval surface at the apex of the sacrum and the base of the coccyx. It is connected by the following ligaments:

- **Interarticular.**
  - Anterior Sacro-coccygeal.
  - Posterior Sacro-coccygeal.
- **Lateral Sacro-coccygeal.**
- **Interposed Fibro-cartilage.**

The **Interarticular Ligaments** connect the cornua of the two bones. The **Anterior Sacro-coccygeal Ligament** consists of a few irregular fibres which descend from the anterior surface of the sacrum to the front of the coccyx, becoming blended with the periosteum.

The **Posterior Sacro-coccygeal Ligaments** are the *superficial* and the *deep*. The *superficial* is a flat band of ligamentous fibres, of a pearly tint, which arises from the margin of the lower orifice of the sacral canal and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal. The *deep* consists of a few fibres, which descend to the coccyx from that part of the sacrum which forms the anterior wall of the lower part of the sacral canal. Its lower end blends with the preceding.

The **Lateral Sacro-coccygeal Ligaments** are ligamentous bands, each of which passes from the inferior lateral angle of the sacrum to the transverse process of the first piece of the coccyx.

A **Fibro-cartilage** is interposed between the contiguous surfaces of the sacrum and coccyx. It is somewhat thicker in front and behind than at the sides. Occasionally, a synovial membrane is found when the coccyx is freely movable, which is more especially the case during pregnancy.

The different segments of the coccyx are connected together by an extension downward of the anterior and posterior sacro-coccygeal ligaments, a thin annular disk of fibro-cartilage being interposed between each of the bones. In the adult male all the pieces become ossified, but in the female this does not commonly occur until a later period of life. The separate segments of the coccyx are first united, and at a more advanced age the joint between the sacrum and coccyx is obliterated.

**Actions.**—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are slightly forward and backward; they are very limited. Their extent increases during pregnancy.

4. **Articulation of the Ossa Pubis** (Fig. 241).

The articulation between the pubic bones is an amphiarthrodial joint, formed by the junction of the two oval articular surfaces of the osa pubis. The articular surface has been described on a former page under the name of *symphysis*, and the same name is given to the joint. The ligaments of this articulation are the

- **Anterior Pubic.**
- **Superior Pubic.**
- **Posterior Pubic.**
- **Subpubic.**
- **Interpubic disk.**
The Anterior Pubic Ligament consists of several superimposed layers which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeurosis of the External oblique and the tendon of the Rectus muscles. The deep fibres pass transversely across the symphysis, and are blended with the fibro-cartilage.

The Posterior Pubic Ligament consists of a few thin, scattered fibres which unite the two pubic bones posteriorly.

The Superior Pubic Ligament is a band of fibres which connects together the two pubic bones superiorly.

The Subpubic Ligament is a thick, triangular arch of ligamentous fibres, connecting together the two pubic bones below and forming the upper boundary of the pubic arch. Above, it is blended with the interarticular fibro-cartilage; laterally it is united with the rami of the os pubis. Its fibres are closely connected and have an arched direction.

The Interpubic Disk consists of a disk of cartilage and fibro-cartilage connecting the surfaces of the pubic bones in front. Each pubic symphysis is covered by a thin layer of hyaline cartilage which is firmly connected to the bone by a series of nipple-like processes which accurately fit within corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by an intermediate stratum of fibrous tissue and fibro-cartilage which varies in thickness in different subjects. It often contains a cavity in its centre, probably formed by the softening and absorption of the fibro-cartilage, since it rarely appears before the tenth year of life, and is not lined by synovial membrane. It is larger in the female than in the male, but it is very questionable whether it enlarges, as was formerly supposed, during pregnancy. It is most frequently limited to the upper and back part of the joint, but it occasionally reaches to the front, and may extend the entire length of the cartilage. This cavity may be easily demonstrated by making a vertical section of the symphysis pubis near its posterior surface.

The Obturator Ligament is more properly regarded as analogous to the muscular fasciae, with which it will be described.

ARTICULATIONS OF THE UPPER EXTREMITY.

The articulations of the upper extremity may be arranged in the following groups: I. Sterno-clavicular articulation. II. Acromio-clavicular articulation. III. Ligaments of the Scapula. IV. Shoulder-joint. V. Elbow-joint. VI. Radio-ulnar articulations. VII. Wrist-joint. VIII. Articulations of the Carpal Bones. IX. Carpo-metacarpal articulations. X. Metacarpo-phalangeal articulations. XI. Articulations of the Phalanges.

I. Sterno-clavicular Articulation (Fig. 242).

The Sterno-clavicular is regarded by most anatomists as an arthrodial joint, but Cruveilhier considers it to be an articulation by reciprocal reception. Probably the former opinion is the correct one, the varied movement which the joint enjoys being due to the interposition of an interarticular fibro-cartilage between the joint surfaces. The parts entering into its formation are the sternal end of the
clavicle, the upper and lateral part of the first piece of the sternum, and the cartilage of the first rib. The articular surface of the clavicle is much larger than that of the sternum, and invested with a layer of cartilage which is considerably thicker than that on the latter bone. The ligaments of this joint are the

Anterior Sterno-clavicular.
Posterior Sterno-clavicular.
Interclavicular.
Costo-clavicular (rhomboid).

Interarticular Fibro-cartilage.

The Anterior Sterno-clavicular Ligament is a broad band of fibres which covers the anterior surface of the articulation, being attached, above, to the upper and front part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, below, to the upper and front part of the first piece of the sternum. This ligament is covered, in front, by the sternal portion of the Sterno-cleido-mastoid and the integument; behind, it is in relation with the interarticular fibro-cartilage and the two synovial membranes.

The Posterior Sterno-clavicular Ligament is a similar band of fibres which covers the posterior surface of the articulation, being attached, above, to the upper and back part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, below, to the upper and back part of the first piece of the sternum. It is in relation, in front, with the interarticular fibro-cartilage and synovial membranes; behind, with the Sterno-hyoid and Sterno-thyroid muscles.

The Interclavicular Ligament is a flattened band which varies considerably in form and size in different individuals; it passes in a curved direction from the upper part of the inner extremity of one clavicle to the other, and is closely attached to the upper margin of the sternum. It is in relation, in front, with the integument; behind, with the Sterno-thyroid muscles.

The Costa-clavicular Ligament (rhomboid) is short, flat, and strong; it is of a rhomboid form, attached, below, to the upper and inner part of the cartilage of the first rib; it ascends obliquely backward and outward, and is attached, above, to the rhomboid depression on the under surface of the clavicle. It is in relation, in front, with the tendon of origin of the Subclavius; behind, with the subclavian vein.

The Interarticular Fibro-cartilage is a flat and nearly circular disk, interposed between the articulating surfaces of the sternum and clavicle. It is attached,

1 According to Bruch, the sternal end of the clavicle is covered by a tissue which is rather fibrous than cartilaginous in structure.
above, to the upper and posterior border of the articular surface of the clavicle; below, to the cartilage of the first rib, at its junction with the sternum; and by its circumference, to the anterior and posterior sterno-clavicular and interclavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre or below. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

Of the two Synovial Membranes found in this articulation, one is reflected from the sternal end of the clavicle over the adjacent surface of the fibro-cartilage and cartilage of the first rib; the other is placed between the articular surface of the sternum and adjacent surface of the fibro-cartilage; the latter is the larger of the two. They seldom contain much synovia.

Actions.—This articulation is the centre of the movements of the shoulder, and admits of a limited amount of motion in nearly every direction—upward, downward, backward, forward—as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of this part of the skeleton with the trunk.

"The movements attendant on elevation and depression of the shoulder take place between the clavicle and the interarticular fibro-cartilage, the bone rotating upon the ligament on an axis drawn from before backward through its own articular facet. When the shoulder is moved forward and backward, the clavicle, with the interarticular fibro-cartilage, rolls to and fro on the articular surface of the sternum, revolving, with a sliding movement, round an axis drawn nearly vertically through the sternum. In the circumduction of the shoulder, which is compounded of these two movements, the clavicle revolves upon the interarticular fibro-cartilage, and the latter, with the clavicle, rolls upon the sternum." 1 Elevation of the clavicle is principally limited by the costo-clavicular ligament; depression, by the interclavicular. The muscles which raise the clavicle, as in shrugging the shoulders, are the upper fibres of the Trapezius, the Levator anguli scapulae, the clavicular head of the Sterno-mastoid, assisted to a certain extent by the two Rhomboids, which pull the inferior angle of the Scapula backward and upward, and so raise the clavicle. The depression of the clavicle is principally effected by gravity, assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. It is drawn backward by the Rhomboids and the middle and lower fibres of the Trapezius, and forward by the Serratus magnus and Pectoralis minor.

Surface Form.—The position of the sterno-clavicular joint may be easily ascertained by feeling the enlarged sternal end of the collar-bone just external to the long, cord-like, sternal origin of the Sterno-mastoid muscle. If this muscle is relaxed by bending the head forward, a depression just internal to the end of the clavicle, and between it and the sternum, can be felt, indicating the exact position of the joint, which is subcutaneous. When the arm hangs by the side, the cavity of the joint is V-shaped. If the arm is raised, the bones become more closely approximated, and the cavity becomes a mere slit.

Surgical Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is to this, and to the fact that the force of the blow is generally transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the bone is generally broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence is applied than upon the anatomical construction of the joint: it may be either forward, backward, or upward. The chief point worthy of note, as regards the construction of the joint, in regard to dislocations, is the fact that, owing to the shape of the articular surfaces being so little adapted to each other, and that the strength of the joint mainly depends upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place.

II. Acromio-clavicular Articulation (Fig. 243).

The Acromio-clavicular is an arthrodial joint formed between the outer extremity of the clavicle and the upper edge of the acromion process of the scapula. Its ligaments are the

1 Humphry, On the Human Skeleton, p. 402.
Superior Acromio-clavicular.
Inferior Acromio-clavicular.
Interarticular Fibro-cartilage.

The Superior Acromio-clavicular Ligament is a broad band, of a quadrilateral form, which covers the superior part of the articulation, extending between the upper part of the outer end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres which interlace with the aponeurosis of the Trapezius and Deltoid muscles; below, it is in contact with the interarticular fibro-cartilage (when it exists) and the synovial membranes.

The Inferior Acromio-clavicular Ligament, somewhat thinner than the preceding, covers the under part of the articulation, and is attached to the adjoining surfaces of the two bones. It is in relation, above, with the synovial membranes, and in rare cases with the interarticular fibro-cartilage; below, with the tendon of the Supraspinatus. These two ligaments are continuous with each other in front and behind, and form a complete capsule round the joint.

The Interarticular Fibro-cartilage is frequently absent in this articulation. When it exists it generally only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely it completely separates the joint into two cavities.

The Synovial Membrane.—There is usually only one synovial membrane in this articulation, but when a complete interarticular fibro-cartilage exists there are two synovial membranes.

The Coraco-clavicular Ligament serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation, but as it forms a most efficient means in retaining the clavicle in contact with the acromial
process, it is usually described with it. It consists of two fasciculi, called the trapezoid and conoid ligaments.

The Trapezoid Ligament, the anterior and external fasciculus, is broad, thin, and quadrilateral; it is placed obliquely between the coracoid process and the clavicle. It is attached, below, to the upper surface of the coracoid process; above, to the oblique line on the under surface of the clavicle. Its anterior border is free; its posterior border is joined with the conoid ligament, the two forming by their junction a projecting angle.

The Conoid Ligament, the posterior and internal fasciculus, is a dense band of fibres, conical in form, the base being turned upward, the summit downward. It is attached by its apex to a rough impression at the base of the coracoid process, internal to the preceding; above, by its expanded base, to the conoid tubercle on the under surface of the clavicle, and to a line proceeding internally from it for half an inch. These ligaments are in relation, in front, with the Subclavians and Deltoid; behind, with the Trapezius. They serve to limit rotation of the scapula, the Trapezoid limiting rotation forward, and the Conoid backward.

Actions.—The movements of this articulation are of two kinds: 1. A gliding motion of the articular end of the clavicle on the acromion. 2. Rotation of the scapula forward and backward upon the clavicle, the extent of this rotation being limited by the two portions of the coraco-clavicular ligament.

The acromo-clavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Sir George Humphry that if there had been no joint between the clavicle and scapula the circular movement of the scapula on the ribs (as in throwing both shoulders backward or forward) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such position, and it would have been impossible to give a blow straight forward with the full force of the arm; that is to say, with the combined force of the scapula, arm, and forearm. "This joint," as he happily says, "is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position or nearly so." Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulders), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Surface Form.—The position of the acromo-clavicular joint can generally be ascertained by the slightly enlarged extremity of the outer end of the clavicle, which causes it to project above the level of the acromion process of the scapula. Sometimes this enlargement is so considerable as to form a rounded eminence, which is easily to be felt. The joint lies in the plane of a vertical line passing up the middle of the front of the arm.

Surgical Anatomy.—Owing to the slanting shape of the articular surfaces of this joint, dislocation generally occurs downward; that is to say, the acromion process of the scapula is dislocated under the outer end of the clavicle; but dislocations in the opposite direction have been described. The displacement is often incomplete, on account of the strong coraco-clavicular ligaments, which remain un torn. The same difficulty exists, as in the sterno-clavicular dislocation, in maintaining the ends of the bone in position after reduction.

III. Proper Ligaments of the Scapula (Fig. 243).

The proper ligaments of the scapula are the

Coraco-acromial. Transverse.

The Coraco-acromial Ligament is a broad, thin, flat band, of a triangular shape, extended transversely above the upper part of the shoulder-joint, between the coracoid and acromial processes. It is attached, by its apex, to the summit of the acromion just in front of the articular surface for the clavicle, and by its broad base to the whole length of the outer border of the coracoid process. Its posterior fibres are directed obliquely backward and inward, its anterior fibres transversely inward. This ligament completes the vault formed by the coracoid and acromion
processes for the protection of the head of the humerus. It is in relation, above, with the clavicle and under surface of the Deltoid; below, with the tendon of the Supraspinatus muscle, a bursa being interposed. Its anterior border is continuous with a dense cellular lamina that passes beneath the Deltoid upon the tendons of the Supra- and Infraspinatus muscles. This ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and base of the coracoid process, and joining together at their attachment into the acromion process. When the Pectoralis minor is inserted, as sometimes is the case, into the capsule of the shoulder-joint, instead of into the coracoid process, it passes between these two bands, and the intervening portion is then deficient.

The Transverse or Coracoïd (suprascapular) Ligament converts the suprascapular notch into a foramen. It is a thin and flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the inner extremity of the scapular notch. The suprascapular nerve passes through the foramen; the suprascapular vessels pass over the ligament.

**Movements of Scapula.**—The scapula is capable of being moved upward and downward, forward and backward, or, by a combination of these movements, circumducted on the wall of the chest. The muscles which raise the scapula are the upper fibres of the Trapezius, the Levator anguli scapulae, and the two Rhomboids; those which depress it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn backward by the Rhomboids and the middle and lower fibres of the Trapezius, and forward by the Serratus magnus and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very considerable, and greatly assists the movements of the arm at the shoulder-joint. Thus, in raising the arm from the side the Deltoid and Supraspinatus can only lift it to a right angle with the trunk, the further elevation of the limb being effected by the Trapezius moving the scapula on the wall of the chest. This mobility is of special importance in ankylosis of the shoulder-joint, the movements of this bone compensating to a very great extent for the immobility of the joint.

**IV. Shoulder-Joint (Fig. 243).**

The Shoulder is an synarthrodial or ball-and-socket joint. The bones entering into its formation are the large globular head of the humerus, which is received into the shallow glenoid cavity of the scapula—an arrangement which permits of very considerable movement, whilst the joint itself is protected against displacement.
by the tendons which surround it and by atmospheric pressure. The ligaments do not maintain the joint surfaces in apposition, because when they alone remain the humerus can be separated to a considerable extent from the glenoid cavity; their use, therefore, is to limit the amount of movement. Above, the joint is protected by an arched vault, formed by the under surface of the coracoide and acromion processes, and the coraco-acromial ligament. The articular surfaces are covered by a layer of cartilage: that on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case in the glenoid cavity. The ligaments of the shoulder are the

**Capsular.**

Coraco-humeral.

**Glenoid.**

Transverse humeral.

The **Capsular Ligament** completely encircles the articulation, being attached, above, to the circumference of the glenoid cavity beyond the glenoid ligament; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage above than in the rest of its extent. It is thicker above and below than elsewhere, and is remarkably loose and lax, and much larger and longer than is necessary to keep the bones in contact, allowing them to be separated from each other more than an inch—an evident provision for that extreme freedom of movement which is peculiar to this articulation. Its superficial surface is strengthened, above, by the Supraspinatus; below, by the long head of the Triceps; posteriorly, by the tendons of the Infraspinatus and Teres minor; and anteriorly, by the tendon of the Subscapularis. The capsular ligament usually presents three openings; one anteriorly, below the coracoid process, establishes a communication between the synovial membrane of the joint and a bursa beneath the tendon of the Subscapularis. The second, which is not constant, exists between the joint and a bursal sac belonging to the Infraspinatus muscle. The third is seen between the two tuberosities, for the passage of the long tendon of the Biceps muscle.

The **Coraco-humeral** is a broad band which strengthens the upper part of the capsular ligament. It arises from the outer border of the coracoid process, and passes obliquely downward and outward to the front of the great tuberosity of the humerus, being blended with the tendon of the Supraspinatus muscle. This ligament is intimately united to the capsular in the greater part of its extent.

The **Transverse Humeral Ligament.**—This is a broad band of fibrous tissue passing from the lesser to the greater tuberosity of the humerus, and always limited to that portion of the bone which lies above the epiphysial line. It converts the bicipital groove into an osseo-aponeurotic canal, and is the analogue of the strong process of bone which connects the summits of the two tuberosities in the musk ox.

**Supplemental Bands of the Capsular Ligament.**—In addition to the coraco-humeral, the capsular ligament is strengthened by supplemental bands in the *interior* of the joint. These bands (*gleno-humeral ligaments*) are situated on the fore part of the capsule, and the *superior* passes from the upper part of the anterior margin of the glenoid cavity to the upper end of the bicipital groove. This is sometimes known as Flood's ligament, and is supposed to correspond with the ligamentum teres of the hip-joint. The *middle* one, from the same origin, passes downward and outward to the lower part of the lesser tuberosity. Between these two is the orifice of the *subscapular bursa*. The *inferior* band passes from the middle of the anterior edge of the glenoid cavity to the under part of the neck of the humerus. The two latter are known as Schlemm's ligaments.

The **Glenoid Ligament** is a fibrous rim attached round the margin of the

---

1 The long tendon of origin of the Biceps muscle also acts as one of the ligaments of this joint. See the observations on p. 318 on the function of the muscles passing over more than one joint.
THE SHOULDER-JOINT.

347

glenoid cavity. It is continuous above with the long tendon of the Biceps, which bifurcates at that point.

The Synovial Membrane is reflected from the margin of the glenoid cavity over the fibro-cartilaginous rim surrounding it: it is then reflected over the internal surface of the capsular ligament, covers the lower part and sides of the neck of the humerus, and is continued a short distance over the cartilage covering the head of the bone. The long tendon of the Biceps muscle which passes through the capsular ligament is enclosed in a tubular sheath of synovial membrane, which is reflected upon it at the point where it perforates the capsule, and is continued around it as far as the summit of the glenoid cavity. The tendon of the Biceps is thus enabled to traverse the articulation, but it is not contained in the interior of the synovial cavity. The synovial membrane communicates with a large bursal sac beneath the tendon of the Subscapularis, by an opening on the anterior side of the capsular ligament; it also occasionally communicates with another bursal sac, beneath the tendon of the Infraspinatus, through an orifice at its posterior part. A third bursal sac, which does not communicate with the joint, is placed between the under surface of the Deltoid and the outer surface of the capsule.

The Muscles in relation with the joint are, above, the Supraspinatus; below, the long head of the Triceps; internally, the Subscapularis; externally, the Infraspinatus and Teres minor; within, the long tendon of the Biceps. The Deltoid is placed most externally, and covers the articulation on its outer side, as well as in front and behind.

The Arteries supplying the joint are articular branches of the anterior and posterior circumflex, and suprascapular.

The Nerves are derived from the circumflex and suprascapular.

Actions.—The shoulder-joint is capable of movement in every direction, forward, backward, abduction, adduction, circumduction, and rotation. The humerus is drawn forward by the Pectoralis major, anterior fibres of the Deltoid, Coracobrachialis, and by the Biceps when the forearm is flexed; backward, by the Latissimus dorsi, Teres major, posterior fibres of the Deltoid, and by the Triceps when the forearm is extended; it is abducted (elevated) by the Deltoid and Supraspinatus; it is adducted (depressed) by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major; it is rotated outward by the Infraspinatus and Teres minor; and it is rotated inward by the Subscapularis, Latissimus dorsi, Teres major, and Pectoralis major.

The most striking peculiarities in this joint are: 1. The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when supplemented by the glenoid ligament. 2. The looseness of the capsule of the joint. 3. The intimate connection of the capsule with the muscles attached to the head of the humerus. 4. The peculiar relation of the biceps tendon to the joint.

It is in consequence of the relative size of the two articular surfaces that the joint enjoys such free movement in every possible direction. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces and by the tension of the corresponding fibres of the capsule, together with that of the muscles acting as accessory ligaments, they can be carried considerably farther by the movements of the scapula, involving, of course, motion at the acromio- and sterno-clavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint. The extent of these movements of the scapula is very considerable, especially in extreme elevation of the arm, which movement is best accomplished when the arm is thrown somewhat forward, since the articular surface of the humerus is broader in the middle than at either end, especially the lower, so that the range of elevation directly forward is less, and that directly backward still more restricted. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the

1 See p. 344.
coracoid process, and the coraco-acromial ligament constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about an inch from the scapula when the muscles are dissected from the capsular ligament and an opening made in it to remove the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere—an arrangement which "renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest" (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that "abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity, adduction by the tension of the coraco-humeral ligament" (Beaunis et Bouchard).

The intimate union of the tendons of the four short muscles with the capsule converts these muscles into elastic and spontaneously acting ligaments of the joint, and it is regarded as being also intended to prevent the folds into which all portions of the capsule would alternately fall in the varying positions of the joint from being driven between the bones by the pressure of the atmosphere.

The peculiar relations of the Biceps tendon to the shoulder-joint appear to subserve various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonizes the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously adverted to.1 Next, it strengthens the upper part of the articular cavity, and prevents the head of the humerus from being pressed up against the acromion process, when the Deltoid contracts, instead of forming the centre of motion in the glenoid cavity. By its passage along the bicipital groove it assists in rendering the head of the humerus steady in the various movements of the arm. When the arm is raised from the side it assists the Supra- and Infraspinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Surface Form.—The direction and position of the shoulder-joint may be indicated by a line drawn from the middle of the coraco-acromial ligament, in a curved direction, with its convexity inward, to the innermost part of that portion of the head of the humerus which can be felt in the axilla when the arm is forcibly abducted from the side. When the arm hangs by the side, not more than one-third of the head of the bone is in contact with the glenoid cavity, and three-quarters of its circumference is in front of a vertical line drawn from the anterior border of the acromion process.

Surgical Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint in the body. Dislocation occurs when the arm is abducted, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front and behind the joint. In consequence of the muscles at the back being stronger than those in front, and especially on account of the long head of the Triceps preventing the bone passing backward, dislocation forward is much more common than backward. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid. Occasionally, in consequence probably of a greater amount of force being brought to bear on the limb, the head is driven farther inward, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid),

1 See p. 318.
and rarely it passes backward and remains in the infraspinatus fossa, beneath the spine (subspinous).

The shoulder-joint is sometimes the seat of all those inflammatory affections, both acute and chronic, which attack joints, though perhaps less frequently than some other joints of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyemia, or may follow secondarily on the so-called acute epiphysitis of infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended and the contour of the joint rounded. Special projections may occur at the site of the openings in the capsular ligament. Thus a swelling may appear just in front of the joint, internal to the lesser tuberosity, from effusion into the bursa beneath the Subscapularis muscle; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoid and Pectoralis major muscles, from effusion into the diverticulum, which runs down the bicipital groove with the tendon of the biceps. The effusion into the synovial membrane can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt.

Tubercular arthritis not unfrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result or long-protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of osteoarthritis, and may also be affected in gout and rheumatism; or in locomotor ataxy, when it becomes the seat of Charcot's disease.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tubercular form) which have gone on to destruction of the articulation; in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain; and possibly in some few cases of growth connected with the upper end of the bone. The operation is best performed by making an incision from the middle of the coraco-acromial ligament down the arm for about three inches; this will expose the bicipital groove and the tendon of the Biceps, which may be either divided or hooked out of the way, according as to whether it is implicated in the disease or not. The capsule is then freely opened, and the muscles attached to the greater and lesser tuberosities of the humerus divided. The head of the bone can then be thrust out of the wound and sawn off, or divided with a narrow saw in situ and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible. The glenoid cavity must then be examined, and gouged if curious.

V. Elbow-Joint.

The Elbow is a ginglymus or hinge-joint. The bones entering into its formation are the trochlear surface of the humerus, which is received into the greater sigmoid cavity of the ulna, and admits of the movements peculiar to this joint—viz. flexion and extension; whilst the lesser, or radial, head of the humerus articulates with the cup-shaped depression on the head of the radius; the circumference of the head of the radius articulates with the lesser sigmoid cavity of the ulna, allowing of the movement of rotation of the radius on the ulna, the chief action of the superior radio-ulnar articulation. The articular surfaces are covered with a thin layer of cartilage, and connected together by a capsular ligament of unequal thickness, being especially thickened on its two sides and, to a less extent, in front and behind. These thickened portions are usually described as distinct ligaments under the following names:

- Anterior.
- Posterior.
- Internal Lateral.
- External Lateral.

The orbicular ligament of the upper radio-ulnar articulation must also be reckoned among the ligaments of the elbow.

The Anterior Ligament (Fig. 245) is a broad and thin fibrous layer which covers the anterior surface of the joint. It is attached to the front of the internal condyle and to the front of the humerus immediately above the coronoid fossa; below, to the anterior surface of the coronoid process of the ulna and orbicular ligament, being continuous on each side with the lateral ligaments. Its superficial fibres pass obliquely from the inner condyle of the humerus outward to the orbicular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but mainly inserted into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in front, with the Brachialis anticus, except at its outermost part; behind, with the synovial membrane.
The **Posterior Ligament** (Fig. 246) is a thin and loose membranous fold, attached, above, to the lower end of the humerus, on a level with the upper part of the olecranon fossa; below, to the margin of the olecranon. The superficial or transverse fibres pass between the adjacent margins of the olecranon fossa. The deeper portion consists of vertical fibres, which pass from the upper part of the olecranon fossa to the margin of the olecranon. This ligament is in relation, behind, with the tendon of the Triceps and the Anconeus; in front, with the synovial membrane.

The **Internal Lateral Ligament** (Fig. 245) is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion. The *anterior portion*, directed obliquely forward, is attached, above, by its apex, to the front part of the internal condyle of the humerus; and, below, by its broad base, to the inner margin of the coronoid process. The *posterior portion*, also of triangular form, is attached, above, by its apex, to the lower and back part of the internal condyle; below, to the inner margin of the olecranon. Between these two bands a few intermediate fibres descend from the internal condyle to blend with a transverse band of ligamentous tissue which bridges across the notch between the olecranon and coronoid processes. This ligament is in relation, internally, with the Triceps and Flexor carpi ulnaris muscles and the ulnar nerve, and gives origin to part of the Flexor sublimis digitorum.

The **External Lateral Ligament** (Fig. 246) is a short and narrow fibrous band, less distinct than the internal, attached, above, to a depression below the external condyle of the humerus; below, to the orbicular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the outer margin of the
ulna. This ligament is intimately blended with the tendon of origin of the Supinator brevis muscle.

The Synovial Membrane is very extensive. It covers the margin of the articular surface of the humerus, and lines the coronoid and olecranon fossae on that bone; from these points it is reflected over the anterior, posterior, and lateral ligaments, and forms a pouch between the lesser sigmoid cavity, the internal surface of the orbicular ligament, and the circumference of the head of the radius.

Between the capsular ligament and the synovial membrane are three masses of fat; one, the largest, above the olecranon fossa, which is pressed into the fossa by the triceps during flexion; a second, over the coronoid fossa; and a third, over the radial fossa. These are pressed into their respective fossae during extension.

The Muscles in relation with the joint are, in front, the Brachialis anticus; behind, the Triceps and Anconeus; externally, the Supinator brevis and the common tendon of origin of the Extensor muscles; internally, the common tendon of origin of the Flexor muscles, and the Flexor carpi ulnaris, with the ulnar nerve.

The Arteries supplying the joint are derived from the communicating branches between the superior profunda, inferior profunda, and anastomotica magna arteries, branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar and the recurrent branch of the radial. These vessels form a complete chain of inosculation around the joint.

The Nerves are derived from the ulnar as it passes between the internal condyle and the olecranon; a filament from the musculo-cutaneous (Rüdinger), and two from the median (Macalister).

Actions.—The elbow-joint comprises three different portions—viz, the joint between the ulna and humerus, that between the head of the radius and the humerus, and the superior radio-ulnar articulation, described below. All these articular surfaces are invested by a common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlear surface of the humerus, this movement does not take place in a straight line; so that when the forearm is extended and supinated the axis of the arm and forearm is not in the same line; but the one portion of the limb forms an angle with the others, and the hand, with the forearm, is directed outward. During flexion, on the other hand, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The shape of the articular surface of the humerus, with its prominences and depressions accurately adapted to the opposing surfaces of the olecranon, prevents any lateral movement. Flexion is produced by the action of the Biceps and Brachialis
The joint between the head of the radius and the capitellum or radial head of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis, and allow of movement in all directions were it not for the orbicular ligament by which the head of the radius is bound down firmly to the sigmoid cavity of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise constantly occur as a consequence of the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament the tendon of the biceps would be liable to pull the head of the radius out of the joint. In complete extension the head of the radius glides so far back on the outer condyle that its edge is plainly felt at the back of the articulation. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint, the limitation of flexion being also aided by the soft structures of the arm and forearm coming in contact.

In combination with any position of flexion or extension the head of the radius can be rotated in the upper radio-ulnar joint, carrying the hand with it. The hand is articulated to the lower surface of the radius only, and the concave or sigmoid surface on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint (as will be seen in the sequel) by the interarticular fibro-cartilage. Thus, rotation of the head of the radius round an axis which passes through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

**Surface Form.**—If the forearm be slightly flexed on the arm, a curved crease or fold with its convexity downward may be seen running across the front of the elbow, extending from one condyle to the other. The centre of this fold is some slight distance above the line of the joint. The position of the radio-humeral portion of the joint can be at once ascertained by feeling for a slight groove or depression between the head of the radius and the capitellum of the humerus at the back of the articulation.

**Surgical Anatomy.**—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong lateral ligaments and the support which the joint derives from the mass of muscles attached to each condyle of the humerus, lateral displacement of the bones is very uncommon, whereas antero-posterior dislocation, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, much more frequently takes place, dislocation backward taking place when the forearm is in a position of extension, and forward when in a position of flexion. For, in the former position, that of extension, the coronoid process is not interlocked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon process is in the olecranon fossa, and entirely prevents displacement forward. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backward, while the olecranon loses its grip and is not so efficient, as during extension, in preventing a forward displacement. When lateral dislocation does take place, it is generally incomplete.

Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation, for, as a rule, fracture of a bone more frequently takes place, under the application of any severe violence, in young persons than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury.

The elbow-joint is occasionally the seat of acute synovitis. The synovial membrane then becomes distended with fluid, the bulging showing itself principally around the olecranon process; that is to say, on its inner and outer sides and above, in consequence of the laxness of the posterior ligament. Occasionally a well-marked, triangular projection may be seen on the outer side of the olecranon, from bulging of the synovial membrane beneath the Anconeus muscle. Again, there is often some swelling just above the head of the radius, in the line of the radio-humeral joint. There is generally not much swelling at the front of the joint, though sometimes deep-seated fulness beneath the Brachialis anticus may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps muscle; occasionally the pus discharges itself in front, near the insertion of the Brachialis anticus muscle. Chronic synovitis,
usually of tubercular origin, is of common occurrence in the elbow-joint; under these circumstances the forearm tends to assume the position of semi-flexion, which is that of greatest ease and relaxation of ligaments. It should be borne in mind, that should ankylosis occur in this or the extended position, the limb will not be nearly so useful as if ankylosed in a position of rather less than a right angle. Loose cartilages are sometimes met with in the elbow-joint, not so commonly, however, as in the knee; nor do they, as a rule, give rise to such urgent symptoms as in this articulation, and rarely require operative interference. The elbow-joint is also sometimes affected with osteo-arthritis, but this affection is less common in this articulation than in some other of the larger joints.

Excision of the elbow is principally required for three conditions: viz. tubercular arthritis, injury and its results, and faulty ankylosis; but may be necessary for some other rarer conditions, such as disorganizing arthritis after pyemia, unreduced dislocations, and osteo-arthritis. The results of the operation are, as a rule, more favorable than those of excision of any other joint, and it is one, therefore, that the surgeon should never hesitate to perform, especially in the first three of the conditions mentioned above. The operation is best performed by a single vertical incision down the back of the joint, a transverse incision, over the outer condyle, being added if the parts are much thickened and fixed. A straight incision is made about four inches long, the mid-point of which is on a level with and a little to the inner side of the tip of the olecranon. This incision is made down to the bone, through the substance of the Triceps muscle. The operator with the point of his knife, and guarding the soft parts with his thumb-nail, separates them from the bone. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which lies parallel to his incision, but a little internal, as it courses down between the internal condyle and the olecranon process, and the prolongation of the Triceps into the deep fascia of the forearm over the Anconens muscle. Having cleared the bones and divided the lateral and posterior ligaments, the forearm is strongly flexed and the ends of the bone turned out and sawn off. The section of the humerus should be through the base of the condyles, that of the ulna and radius should be just below the level of the lesser sigmoid cavity of the ulna and the neck of the radius. In this operation the object is to obtain such union as shall allow free motion of the bones of the forearm; and, therefore, passive motion must be commenced early, that is to say, about the tenth day.

VI. Radio-ulnar Articulations.

The articulation of the radius with the ulna is effected by ligaments which connect together both extremities as well as the shafts of these bones. They may, consequently, be subdivided into three sets: 1, the superior radio-ulnar, which is a portion of the elbow-joint; 2, the middle radio-ulnar; and, 3, the inferior radio-ulnar articulations.

This articulation is a trochoid or pivot-joint. The bones entering into its formation are the inner side of the circumference of the head of the radius rotating within the lesser sigmoid cavity of the ulna. Its only ligament is the annular or orbicular.

The Orbicular Ligament (Fig. 246) is a strong, flat band of ligamentous fibres, which surrounds the head of the radius, and retains it in firm connection with the lesser sigmoid cavity of the ulna. It forms about four-fifths of a fibrous ring, attached by each end to the extremities of the lesser sigmoid cavity, and is smaller at the lower part of its circumference than above, by which means the head of the radius is more securely held in its position. Its outer surface, is strengthened by the external lateral ligament of the elbow, andaffords origin to part of the Supinator brevis muscle. Its inner surface is smooth, and lined by synovial membrane. The synovial membrane is continuous with that which lines the elbow-joint.

Actions.—The movement which takes place in this articulation is limited to rotation of the head of the radius within the orbicular ligament, and upon the lesser sigmoid cavity of the ulna, rotation forward being called pronation; rotation backward, supination. Supination is performed by the Biceps and Supinator brevis, assisted to a slight extent by the Extensor muscles of the thumb and, in certain positions, by the Supinator longus. Pronation is performed by the Pronator radii teres and the Pronator quadratus, assisted, in some positions, by the Flexor carpi radialis.

Surface Form.—The position of the superior radio-ulnar joint is marked on the surface of
the body by the little dimple on the back of the forearm which indicates the position of the head of the radius.

**Surgical Anatomy.**—Dislocation of the head of the radius alone is not an uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the orbicular ligament.

2. **Middle Radio-ulnar Articulation.**

The interval between the shafts of the radius and ulna is occupied by two ligaments.

**Oblique.**

The **Oblique or Round Ligament** (Fig. 245) is a small, flattened fibrous band which extends obliquely downward and outward from the tuberele of the ulna at the base of the coronoid process to the radius a little below the bicipital tuberosity. Its fibres run in the opposite direction to those of the interosseous ligament, and it appears to be placed as a substitute for it in the upper part of the interosseous interval. This ligament is sometimes wanting.

The **Interosseous Membrane** is a broad and thin plane of fibrous tissue descending obliquely downward and inward, from the interosseous ridge on the radius to that on the ulna. It is deficient above, commencing about an inch beneath the tuberele of the radius; is broader in the middle than at either extremity; and presents an oval aperture just above its lower margin for the passage of the anterior interosseous vessels to the back of the forearm. This ligament serves to connect the bones and to increase the extent of surface for the attachment of the deep muscles. Between its upper border and the oblique ligament an interval exists through which the posterior interosseous vessels pass. Two or three fibrous bands are occasionally found on the posterior surface of this membrane which descend obliquely from the ulna toward the radius, and which have consequently a direction contrary to that of the other fibres. It is in relation, in front, by its upper three-fourths with the Flexor longus pollicis on the outer side, and with the Flexor profundus digitorum on the inner, lying upon the interval between which are the anterior interosseous vessels and nerve; by its lower fourth, with the Pronator quadratus; behind, with the Supinator brevis, Extensor ossis metacarpi
pollicis. Extensor brevis pollicis, Extensor longus pollicis, Extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

This is a pivot-joint, formed by the head of the ulna received into the sigmoid cavity at the inner side of the lower end of the radius. The articular surfaces are covered by a thin layer of cartilage, and connected together by the following ligaments:

Interarticular Fibro-cartilage.

The Anterior Radio-ulnar Ligament (Fig. 248) is a narrow band of fibres extending from the anterior margin of the sigmoid cavity of the radius to the anterior surface of the head of the ulna.

The Posterior Radio-ulnar Ligament (Fig. 249) extends between similar points on the posterior surface of the articulation.

Fig. 249.—Ligaments of wrist and hand. Posterior view.

The Interarticular Fibro-cartilage (Fig. 251) is triangular in shape, and is placed transversely beneath the head of the ulna, binding the lower end of this bone and the radius firmly together. Its circumference is thicker than its centre, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone; and by its base, which is thin, to the prominent edge of the radius, which separates the sigmoid cavity from the carpal articulating surface. Its margins are united to the ligaments of the wrist-joint. Its upper surface, smooth and concave, articulates with the head of the ulna, forming an arthrodiadial joint; its under surface, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform bone. Both surfaces are lined by a synovial membrane—the upper surface, by one peculiar to the radio-ulnar articulation; the under surface, by the synovial membrane of the wrist.

The Synovial Membrane (Fig. 251) of this articulation has been called, from its extreme looseness, the membrana sacciformis; it extends horizontally inward between the head of the ulna and the interarticular fibro-cartilage, and upward between the radius and the ulna, forming here a very loose cul-de-sac. The quantity of synovia which it contains is usually considerable.

Actions.—The movement in the inferior radio-ulnar articulation is just the reverse of that between the two bones above. It consists of a movement of rota-
tion of the lower end of the radius round an axis which corresponds to the centre of the head of the ulna. When the radius rotates forward, pronation of the forearm and hand is the result; and when backward, supination. It will thus be seen that in pronation and supination of the forearm and hand the radius describes a segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement, however, the ulna is not quite stationary, but is circumducted a little in the opposite direction. So that it also describes the segment of a cone, though of smaller size than that described by the radius. The movement which causes this alteration in the position of the head of the ulna takes place principally at the shoulder-joint by a rotation of the humerus, but possibly also to a slight extent at the elbow-joint.¹

Surface Form.—The position of the inferior radio-ulnar joint may be ascertained by feeling for a slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

VII. Radio-carpal or Wrist-joint.

The Wrist is a condyloid articulation. The parts entering into its formation are the lower end of the radius and under surface of the interarticular fibro-cartilage, which form together the receiving cavity, and the scaphoid, semilunar, and cuneiform bones, which form the condyle. The articular surface of the radius and the under surface of the inter-articular fibro-cartilage are the receiving cavity, forming together a transversely elliptical concave surface. The articular surfaces of the scaphoid, semilunar, and cuneiform bones form together a smooth, convex surface, the condyle, which is received into the concavity above mentioned. All the bony surfaces of the articulation are covered with cartilage, and connected together by a capsule, which is divided into the following ligaments:

- External Lateral.
- Anterior.
- Internal Lateral.
- Posterior.

The External Lateral Ligament (radio-carpal) (Fig. 248) extends from the summit of the styloid process of the radius to the outer side of the scaphoid, some of its fibres being prolonged to the trapezium and annular ligament.

The Internal Lateral Ligament (ulno-carpal) is a rounded cord, attached, above, to the extremity of the styloid process of the ulna, and dividing below into two fasciculi, which are attached, one to the inner side of the cuneiform bone, the other to the pisiform bone and annular ligament.

The Anterior Ligament is a broad membranous band, attached, above, to the anterior margin of the lower end of the radius, its styloid process and the ulna; its fibres pass downward and inward to be inserted into the palmar surface of the scaphoid, semilunar, and cuneiform bones, some of the fibres being continued to the os magnum. In addition to this broad membrane, there is a distinct rounded fasciculus, superficial to the rest, which passes from the base of the styloid process of the ulna to the semilunar and cuneiform bones. This ligament is per-

forated by numerous apertures for the passage of vessels, and is in relation, in front, with the tendons of the Flexor profundus digitorum and Flexor longus pollicis; behind, with the synovial membrane of the wrist-joint.

The Posterior Ligament (Fig. 245), less thick and strong than the anterior, is attached, above, to the posterior border of the lower end of the radius; its fibres pass obliquely downward and inward, to be attached to the dorsal surface of the scaphoid, semilunar, and cuneiform bones, being continuous with those of the dorsal carpal ligaments. This ligament is in relation, behind, with the extensor tendons of the fingers; in front, with the synovial membrane of the wrist.

The Synovial Membrane (Fig. 251) lines the inner surface of the ligaments above described, extending from the lower end of the radius and interarticular fibro-cartilage above to the articular surfaces of the carpal bones below. It is loose and lax, and presents numerous folds, especially behind.

Relations.—The wrist-joint is covered in front by the flexor and behind by the extensor tendons; it is also in relation with the radial and ulnar arteries.

The Arteries supplying the joint are the anterior and posterior carpal branches of the radial and ulnar, the anterior and posterior interosseous, and some ascending branches from the deep palmar arch.

The Nerves are derived from the ulnar and posterior interosseous.

Actions.—The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. Its actions will be further studied with those of the carpus, with which they are combined.

Surface Form.—The line of the radio-carpal joint is on a level with the apex of the styloid process of the ulna.

Surgical Anatomy.—The wrist-joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movement which takes place between the several bones serves to break the jars that result from falls or blows on the hand. Dislocation backward, which is the more common, simulates to a considerable extent Colles’ fracture of the radius, and is liable to be mistaken for it. The diagnosis can be easily made out by observing the relative position of the styloid processes of the radius and the ulna. In the natural condition the styloid process of the radius is on a lower level—i.e. nearer the ground—when the arm hangs by the side, than that of the ulna, and the same would be the case in dislocation. In Colles’ fracture, on the other hand, the styloid process of the radius is on the same, or even a higher level than that of the ulna.

The wrist-joint is occasionally the seat of acute synovitis, the result of traumaticism or arising in the rheumatic or pyemic state. When the synovial sac is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighborhood. Chronic inflammation of the wrist is generally tubercular, and often leads to similar disease in the synovial sheaths of adjacent tendons and of the intercarpal joints. The disease, therefore, when progressive, often leads to necrosis of the carpal bones, and the result is often unsatisfactory.

VIII. Articulations of the Carpus.

These articulations may be subdivided into three sets:

1. The Articulations of the First Row of Carpal Bones.
2. The Articulations of the Second Row of Carpal Bones.
3. The Articulations of the Two Rows with each other.

1. ARTICULATIONS OF THE FIRST ROW OF CARPAL BONES.

These are arthrodial joints. The ligaments connecting the scaphoid, semilunar, and cuneiform bones are—

Dorsal. Two Interosseous. Palmar.

The Dorsal Ligaments are placed transversely behind the bones of the first row; they connect the scaphoid and semilunar and the semilunar and cuneiform.

The Palmar Ligaments connect the scaphoid and semilunar and the semilunar
and cuneiform bones; they are less strong than the dorsal, and placed very deeply under the anterior ligament of the wrist.

The **Intertosseous Ligaments** (Fig. 251) are two narrow bundles of fibrous tissue connecting the semilunar bone on one side with the scaphoid, and on the other with the cuneiform. They are on a level with the superior surfaces of these bones, and close the upper part of the spaces between them. Their upper surfaces are smooth, and form with the bones the convex articular surfaces of the wrist-joint.

The ligaments connecting the pisiform bone are—

Capsular. Two Palmar ligaments.

The **Capsular Ligament** is a thin membrane which connects the pisiform bone to the cuneiform. It is lined with a separate synovial membrane.

The **two Palmar Ligaments** are two strong fibrous bands which connect the pisiform to the unciform, the *piso-uncinate*, and to the base of the fifth metacarpal bone, the *piso-metacarpal ligament* (Fig. 248).

2. **Articulations of the Second Row of Carpal Bones.**

These are also arthrodiel joints. The articular surfaces are covered with cartilage, and connected by the following ligaments:

Dorsal. Palmar.

Three Intertosseous.

The **Dorsal Ligaments** extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the os magnum, and the os magnum with the unciform.

The **Palmar Ligaments** have a similar arrangement on the palmar surface.

The **three Intertosseous Ligaments**, much thicker than those of the first row, are placed one between the os magnum and the unciform, a second between the os magnum and the trapezoid, and a third between the trapezium and trapezoid. The first of these is much the strongest, and the third is sometimes wanting. Sometimes a slender interosseous band connects the os magnum and the scaphoid.

3. **Articulations of the Two Rows of Carpal Bones with Each Other.**

The joint between the scaphoid, semilunar, and cuneiform, and the second row of the carpus, or the *mid-carpal joint*, is made up of three distinct portions; in the centre the head of the os magnum and the superior margin of the unciform articulate with the deep, cup-shaped cavity formed by the scaphoid and semilunar bones, and constitute a sort of ball-and-socket joint. On the outer side the trapezium and trapezoid articulate with the scaphoid, and on the inner side the unciform articulates with the cuneiform, forming gliding joints.

The ligaments are—

Anterior or Palmar. External Lateral.

Posterior or Dorsal. Internal Lateral.

The **Anterior or Palmar Ligaments** consist of short fibres, which pass, for the most part, from the palmar surface of the bones of the first row to the front of the os magnum.

The **Posterior or Dorsal Ligaments** consist of short, irregular bundles of fibres passing between the bones of the first and second row on the dorsal surface of the carpus.

The **Lateral Ligaments** are very short: they are placed, one on the radial, the other on the ulnar side of the carpus; the former, the stronger and more distinct, connecting the scaphoid and trapezium bones, the latter the cuneiform and unciform; they are continuous with the lateral ligaments of the wrist-joint.

The **Synovial Membrane of the Carpus** is very extensive: it passes from the
under surface of the scaphoid, semilunar, and cuneiform bones to the upper surface of the bones of the second row, sending upward two prolongations—between the scaphoid and semilunar and the semilunar and cuneiform; sending downward three prolongations between the four bones of the second row, which are further continued onward into the carpo-metacarpal joints of the four inner metacarpal bones, and also for a short distance between the metacarpal bones. There is a separate synovial membrane between the pisiform and cuneiform bones.

**Actions.**—The articulation of the hand and wrist, considered as a whole, is divided into three parts: (1) the radius and the interarticular fibro-cartilage; (2) the meniscus, formed by the scaphoid, semilunar, and cuneiform, the pisiform bone having no essential part in the movements of the hand; (3) the hand proper, the metacarpal bones with the four carpal bones on which they are supported—viz. the trapezium, trapezoid, os magnum, and unciform. These three elements form two joints: (1) the superior (wrist-joint proper), between the meniscus and bones of the forearm; (2) the inferior, between the hand and meniscus (transverse or mid-carpal joint).

(1) The articulation between the forearm and carpus is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than flexion is permitted on account of the articulating surfaces extending farther on the dorsal than on the palmar aspect of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. Of these the former is considerably greater in extent than the latter. In this movement the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist. Finally, circumduction is permitted by the consecutive movements of adduction, extension, abduction, and flexion, with intermediate movements between them. There is no rotation, but this is provided for by the supination and pronation of the radius on the ulna. The movement of flexion is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; extension, by the Extensor carpi radialis longior et brevior and the Extensor carpi ulnaris; adduction (ulnar flexion), by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and abduction (radial flexion), by the Extensors of the thumb and the Extensor carpi radialis longior et brevior and the Flexor carpi radialis.

(2) The chief movements permitted in the transverse or mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which is the movement most freely enjoyed, the trapezium and trapezoid on the radial side and the unciform on the ulnar side glide forward and backward on the scaphoid and cuneiform respectively, while the head of the os magnum and the superior surface of the unciform rotate in the cup-shaped cavity of the scaphoid and semilunar. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the os magnum rotating round a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral portions of the joint.

**IX. Carpo-metacarpal Articulations.**

1. **Articulation of the Metacarpal Bone of the Thumb with the Trapeziun.**

This is a joint of reciprocal reception, and enjoys great freedom of movement, on account of the configuration of its articular surfaces, which are saddle-shaped, so that, on section, each bone appears to be received into a cavity in the other, according to the direction in which they are cut. Its ligaments are a capsular ligament and a synovial membrane.

The **Capsular Ligament** is a thick but loose capsule which passes from the circumference of the upper extremity of the metacarpal bone to the rough edge
bounding the articular surface of the trapezium; it is thickest externally and behind, and lined by a separate synovial membrane.

**Movements.**—In the articulation of the metacarpal bone of the thumb with the trapezium the movements permitted are flexion, extension, adduction, abduction, and circumduction. When the joint is flexed the metacarpal bone is brought in front of the palm and the thumb is gradually turned to the fingers. It is by this peculiar movement that the tip of the thumb is opposed to the other digits; for by slightly flexing the fingers the palmar surface of the thumb can be brought in contact with their palmar surfaces one after another.

2. **Articulations of the Metacarpal Bones of the Four Inner Fingers with the Carpus.**

The joints formed between the carpus and four inner metacarpal bones are arthrodial joints. The ligaments are—

**Dorsal.**

**Palmar.**

**Interosseous.**

The **Dorsal Ligaments**, the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surface. The second metacarpal bone receives two fasciculi—one from the trapezium, the other from the trapezoid; the third metacarpal receives two—one from the trapezoid and one from the os magnum; the fourth two—one from the os magnum and one from the unciform; the fifth receives a single fasciculus from the unciform bone, which is continuous with a similar ligament on the palmar surface, forming an incomplete capsule.

The **Palmar Ligaments** have a somewhat similar arrangement on the palmar surface, with the exception of the third metacarpal, which has three ligaments—an external one from the trapezium, situated above the sheath of the tendon of the Flexor carpi radialis; a middle one, from the os magnum; and an internal one, from the unciform.

The **Interosseous Ligaments** consist of short, thick fibres, which are limited to one part of the carpo-metacarpal articulation; they connect the contiguous inferior angles of the os magnum and unciform with the adjacent surfaces of the third and fourth metacarpal bones.

The **Synovial Membrane** is a continuation of that between the two rows of carpal bones. Occasionally, the articulation of the unciform with the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (Fig. 251) are thus seen to be five in number. The **first**, the membrana sacciformis, passes from the lower end of the ulna to the sigmoid cavity of the radius, and lines the upper surface of the interarticular fibro-cartilage. The **second** passes from the lower end of the radius and interarticular fibro-cartilage above to the bones of the first row below. The **third**, the most extensive, passes between the contiguous margins of the two rows of carpal bones—between the bones of the second row to the carpal...
extremities of the four inner metacarpal bones. The fourth, from the margin of the trapezium to the metacarpal bone of the thumb. The fifth, between the adjacent margins of the cuneiform and pisiform bones.

**Actions.**—The movement permitted in the carpo-metacarpal articulations of the four inner fingers is limited to a slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. Thus the articulation of the metacarpal bone of the little finger is most movable, then that of the ring finger. The metacarpal bones of the index and middle fingers are almost immovable.

3. **Articulations of the Metacarpal Bones with Each Other.**

The carpal extremities of the four inner metacarpal bones articulate with one another at each side by small surfaces covered with cartilages, and connected together by dorsal, palmar, and interosseous ligaments.

The **Dorsal** and **Palmar Ligaments** pass transversely from one bone to another on the dorsal and palmar surfaces. The **Interosseous Ligaments** pass between their contiguous surfaces, just beneath their lateral articular facets.

The **Synovial Membrane** between the lateral facets is a reflection from that between the two rows of carpal bones.

The **Transverse Metacarpal Ligaments** (Fig. 252) is a narrow fibrous band which passes transversely across the anterior surfaces of the digital extremities of the four inner metacarpal bones, connecting them together. It is blended anteriorly with the anterior (glenoid) ligament of the metacarpal-phalangeal articulations. To its posterior border is connected the fascia which covers the interosseous muscles. Its superficial surface is concave where the flexor tendons pass over it. Beneath it the tendons of the interosseous muscles pass to their insertion.

**X. Metacarpo-phalangeal Articulations** (Fig. 252).

These articulations are of the condyloid kind, formed by the reception of the rounded head of the metacarpal bone into a superficial cavity in the extremity of the first phalanx. The ligaments are—

**Anterior.**

Two Lateral.

The **Anterior Ligaments** (*Glenoid Ligaments* of Cruveilhier) are thick, dense, fibrous structures, placed on the palmar surface of the joints in the intervals between the lateral ligaments, to which they are connected; they are loosely united to the metacarpal bone, but very firmly to the base of the first phalanges. Their palmar surface is intimately blended with the transverse metacarpal ligament, and presents a groove for the passage of the flexor tendons, the
sheath surrounding which is connected to each side of the groove. By their deep surface they form part of the articular surface for the head of the metacarpal bone, and are lined by a synovial membrane.

The Lateral Ligaments are strong, rounded cords placed one on each side of the joint, each being attached by one extremity to the posterior tubercle on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

Actions.—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the lateral movements are very limited.

Surface Form.—The prominences of the knuckles do not correspond to the position of the joints either of the metacarpo-phalangeal or interphalangeal articulations. These prominences are invariably formed by the distal ends of the proximal bone of each joint, and the line indicating the position of the joint must be sought considerably in front of the middle of the knuckle. The usual rule for finding these joints is to flex the distal phalanx on the proximal one to a right angle; the position of the joint is then indicated by an imaginary line drawn along the middle of the lateral aspect of the proximal phalanx.

XI. Articulations of the Phalanges.

These are ginglymus joints. The ligaments are—

Anterior. Two Lateral.

The arrangement of these ligaments is similar to those in the metacarpo-phalangeal articulations; the extensor tendon supplies the place of a posterior ligament.

Actions.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

**ARTICULATIONS OF THE LOWER EXTREMITY.**

The articulations of the Lower Extremity comprise the following groups: I. The hip-joint. II. The knee-joint. III. The articulations between the tibia and fibula. IV. The ankle-joint. V. The articulations of the tarsus. VI. The tarso-metatarsal articulations. VII. The metatarso-phalangeal articulations. VIII. The articulations of the phalanges.

I. Hip-joint (Fig. 253).

This articulation is an enarthrodial or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articular surfaces are covered with cartilage, that on the head of the femur being thicker at the centre than at the circumference, and covering the entire surface, with the exception of a depression just below its centre for the ligamentum teres; that covering the acetabulum is much thinner at the centre than at the circumference. It forms an incomplete cartilaginous ring of a horseshoe shape, deficient below and in front, and having in its centre a circular depression, which is occupied in the recent state by a mass of fat covered by synovial membrane. The ligaments of the joints are the

- Capsular.
- Ilio-femoral.
- Transverse.

The Capsular Ligament is a strong, dense, ligamentous capsule, embracing the margin of the acetabulum above and surrounding the neck of the femur below. Its upper circumference is attached to the acetabulum, above and behind, two or three lines external to the cotyloid ligament; but in front it is attached to the outer margin of this ligament, and opposite to the notch where the margin of this cavity is deficient, it is connected to the transverse ligament, and by a few fibres
to the edge of the obturator foramen. Its lower circumference surrounds the neck of the femur, being attached, in front, to the spiral or anterior intertrochanteric line; above, to the base of the neck; behind, to the neck of the bone, about half an inch above the posterior intertrochanteric line. From this insertion the fibres are reflected upward over the neck of the femur, forming a sort of tubular sheath (the cervical reflection), which blends with the periosteum and can be traced as far as the articular cartilage. It is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required, than below and internally, where it is thin, loose, and longer than in any other part. It consists of two sets of fibres, circular and longitudinal. The circular fibres are most abundant at the lower and back part of the capsule, while the longitudinal fibres are greatest in

![Fig. 253.—Left hip-joint laid open.](image)

amount at the upper and front part of the capsule, where they form distinct bands or accessory ligaments, of which the most important is the ilio-femoral. The other accessory bands are known as the pubo-femoral, passing from the ilipectineal eminence to the front of the capsule; ilio-trochanteric, from the anterior inferior spine of the ilium to the front of the great trochanter; and ischio-capsular, passing from the ischium, just below the acetabulum, to blend with the circular fibres at the lower part of the joint. The external surface (Fig. 239, page 337) is rough, covered by numerous muscles, and separated in front from the Psoas and Iliacus by a synovial bursa, which not unfrequently communicates, by a circular aperture, with the cavity of the joint. It differs from the capsular ligament of the shoulder in being much less loose and lax, and in not being perforated for the passage of a tendon.

The Ilio-femoral Ligament (Figs. 239 and 254) is an accessory band of fibres extending obliquely across the front of the joint; it is intimately connected with the capsular ligament, and serves to strengthen it in this situation. It is attached, above, to the lower part of the anterior inferior spine of the ilium; and, diverging below, forms two bands, of which one passes downward to be inserted into the
lower part of the anterior intertrochanteric line; the other passes downward
and outward to be inserted into the upper part of the same line and adjacent
part of the neck of the femur. Between the two bands is a thinner part of
the capsule. Sometimes there is no division, but the ligament spreads out into a flat,
triangular band, which is attached below into the whole length of the anterior in-
trochanteric line. This ligament is frequently called the Y-shaped ligament of
Bigelow. Its upper band is the ilio-trochanteric ligament.

The Ligamentum Teres is a triangular band implanted by its apex into the
depression a little behind and below the centre of the head of the femur, and
by its broad base into the margins of the cotyloid notch, becoming blended with
the transverse ligament. It is formed of connective tissue, surrounded by a tubular
sheath of synovial membrane. Sometimes only the synovial fold exists, or the
ligament may be altogether absent. The ligament is made tense when the hip is
semiflexed, and the limb then adducted and rotated outward; it is, on the other hand,
relaxed when the limb is abducted. It has, however, but little influence as a ligament,
though it may to a certain extent limit move-
ment, and would appear to be merely a modi-
fication of the folds which in other joints

The Cotyloid Ligament is a fibro-cartilaginous rim attached to the margin of
the acetabulum, the cavity of which deepens; at the same time it protects the
edges of the bone and fills up the inequalities on its surface. It bridges over the
notch as the transverse ligament, and thus forms a complete circle, which closely
surrounds the head of the femur, and assists in holding it in its place, acting as a
sort of valve. It is prismoid in form, its base being attached to the margin of
the acetabulum, and its opposite edge being free and sharp; whilst its two surfaces
are invested by synovial membrane, the external one being in contact with the
capsular ligament, the internal one being inclined inward, so as to narrow the
acetabulum and embrace the cartilaginous surface of the head of the femur. It
is much thicker above and behind than below and in front, and consists of close,
compact fibres, which arise from different points of the circumference of the
acetabulum and interlace with each other at very acute angles.

The Transverse Ligament is in reality a portion of the cotyloid ligament,
though differing from it in having no nests of cartilage-cells amongst its fibres. It consists of strong, flattened fibres, which cross the notch at the lower part of the acetabulum and convert it into a foramen. Thus an interval is left beneath the ligament for the passage of nutrient vessels to the joint.

The Synovial Membrane is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers all that portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsular ligament, covers both surfaces of the cotyloid ligament and the mass of fat contained in the depression at the bottom of the acetabulum, and is prolonged in the form of a tubular sheath around the ligamentum teres as far as the head of the femur.

The muscles in relation with the joint are, in front, the Psoas and Iliacus, separated from the capsular ligament by a synovial bursa; above, the reflected head of the Rectus and Gluteus minimus, the latter being closely adherent to the capsule; internally, the Obturator externus and Pectineus; behind, the Pyriformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris (Fig. 256).

The arteries supplying the joint are derived from the obturator, sciatic, internal circumflex, and gluteal.

The nerves are articular branches from the sacral plexus, great sciatic, obturator, accessory obturator, and a filament from the branch of the anterior crural supplying the Rectus.

**Actions.**—The movements of the hip, like those of all enarthrodial joints, are very extensive; they are flexion, extension, adduction, abduction, circumduction, and rotation.

The hip-joint presents a very striking contrast to the other great enarthrodial joint—the shoulder—in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as we have seen, the head of the humerus is not adapted at all in shape to the glenoid cavity, and is
hardly restrained in any of its ordinary movements by the capsular ligament. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for a distance extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the ligamentous ring of the cotyloid ligament, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided (Humphry). The anterior portion of the capsule, described as the ilio-femoral or accessory ligament, is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue, the action of the extensor muscles of the buttock being balanced by the tension of the ilio-femoral and capsular ligaments. The security of the joint may be also provided for by the two bones being directly united through the ligamentum teres; but it is doubtful whether this so-called ligament can have much influence upon the mechanism of the joint. Flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact; extension, by the tension of the ilio-femoral ligament and front of the capsule; adduction, by the thighs coming into contact; adduction, with flexion by the outer band of the ilio-femoral ligament, the ilio-trochanteric ligament, the outer part of the capsular ligament; abduction, by the inner band of the ilio-femoral ligament and the pubo-femoral band; rotation outward, by the outer band of the ilio-femoral ligament; and rotation inward, by the ischio-capsular ligament and the hinder part of the capsule. The muscles which flex the femur on the pelvis are the Psoas, Iliacus, Rectus, Sartorius, Pectineus, Adductor longus and brevis, and the anterior fibres of the Gluteus medius and minimus. Extension is mainly performed by the Gluteus maximus, assisted by the hamstring muscles. The thigh is adducted by the Adductor magnus, longus and brevis, the Pectineus, and Gracilis, and abducted by the Gluteus maximus, medius, and minimus. The muscles which rotate the thigh inward are the anterior fibres of the Gluteus medius, the Gluteus minimus, and the Tensor vagine femoris; while those which rotate it outward are the posterior fibres of the Gluteus medius, the Pyriformis, Obturator externus and internus, Gemellus superior and inferior, Quadratus femoris, Psoas, Iliacus, Gluteus maximus, the three Adductors, the Pectineus, and the Sartorius.

**Surface Form.**—A line drawn from the anterior superior spinous process of the ilium to the most prominent part of the tuberosity of the ischium (Nelaton’s line) runs through the centre of the acetabulum, and would, therefore, indicate the level of the hip-joint; or, in other words, the upper border of the great trochanter, which lies on Nelaton’s line, is on a level with the centre of the hip-joint.

**Surgical Anatomy.**—In dislocation of the hip “the head of the thigh-bone may rest at any point around its socket” (Bryant); but whatever position the head ultimately assumes, the primary displacement is generally downward and inward, the capsule giving way at its weakest—that is, its lower and inner—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the ilio-femoral ligament, which is not easily ruptured. When, for instance, the head is forced backward, this ligament forms a fixed axis, round which the head of the bone rotates, and is thus driven on to the dorsum of the ilium. The ilio-femoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backward it is tense, and produces inversion of the limb; in the dislocation on to the pubes it is relaxed, and therefore allows the external rotators to evert the thigh; while in the thyroid dislocation it is tense and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the bone. But Bigelow has endeavored to show that the Obturator internus is the principal agent in determining whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium or in or near the sciatic notch. In both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow asserts, in the dislocation on to the dorsum, the head of the bone travels up behind the acetabulum, between the muscle and the pelvis; while in the disloc-
tion into the sciatic notch, the head passes behind the muscle, and is therefore prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and so remains in the neighborhood of the sciatic notch. Bigelow, therefore, distinguishes these two forms of dislocation by describing them as dislocations backward, "above and below," the Obturator internus.

The ilio-femoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as a fulcrum to a lever, of which the long arm is the shaft of the femur, and the short arm the neck of the bone.

The hip-joint is rarely the seat of acute synovitis from injury; on account of its deep position and its thick covering of soft parts. Acute inflammation may, and does, frequently occur as the result of constitutional conditions, as rheumatism, pyemia, etc. When, in these cases, effusion takes place, and the joint becomes distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just internal to the ilio-femoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much more frequently of a chronic character and is usually of a tubercular origin. It begins either in the bones or in the synovial membrane, more frequently in the former, and probably, in most cases, at the growing, highly vascular tissue in the neighborhood of the epiphyseal cartilage. In this respect it differs very materially from tubercular arthritis of the knee, where the disease usually commences in the synovial membrane. The reasons for this are twofold: first, this part being the centre of rapid growth, its nutrition is unstable and apt to pass into inflammatory action; and, secondly, great strain is thrown upon it, from the frequency of falls and blows upon the hip, which causes crushing of the epiphyseal cartilage or the cancellous tissue in its neighborhood, with the results likely to follow in an injury. In addition to these, the depth of the joint protects it from the causes of synovitis.

In chronic hip-disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case the limb is flexed, abducted; and rotated outward. In this position all the ligaments of the joint are relaxed: the front of the capsule by flexion; the outer band of the ilio-femoral ligament by abduction; and the inner band of this ligament and the back of the capsule by rotation outward. It is, therefore, the position of the greatest ease. The condition is not quite obvious at first upon examining a patient. If the patient is laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be found that the pelvis is tilted downward on the diseased side and the limb apparently longer than its fellow, and that the lumbar spine is arching forward (lordosis). If now the thigh is abducted and flexed, the tilting downward and the arching forward of the pelvis disappears. The condition is thus explained. A limb which is flexed and abducted is obviously useless for progression, and, in order to overcome the difficulty, the patient depresses the affected side of his pelvis in order to produce parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downward instead of forward. In the latter stages of the disease the limb becomes flexed and abducted and inverted. This position probably depends upon muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex action by the irritation of the peripheral terminations of this nerve in the inflamed articulation. Obturator arthritis is not uncommon in the hip-joint, and it is said to be more common in the male than in the female. The hip-joint is more frequently affected. It is a disease of middle age or more advanced period of life.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum illii. It gives rise to extreme lordosis, and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially gunshot. It may be performed either by an anterior incision or a posterior one. The former one entails less interference with important structures, especially muscles, than the posterior one, but permits of less efficient drainage. In these days, however, when the surgeon aims at securing healing of his wound without suppuration, this second desideratum is not of so much importance. An incision three to four inches in length, starting immediately below and external to the anterior superior spineous process of the ilium, downward and inward between the Sartorius and Tensor fasciae latae, to the neck of the bone, dividing the capsule at its upper part. A narrow-bladed saw now divides the neck of the femur, and the head of the bone is extricated with sequester forceps. All diseased tissue is carefully removed with a sharp spoon or scissors, and the cavity thoroughly flushed out with a hot antisepctic fluid.

The posterior method consists in making an incision three or four inches long, commencing midway between the top of the great trochanter and the anterior superior spine, and ending over the shaft, just below the trochanter. The muscles are detached from the great trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and the bone sawn through just below the top of the trochanter with a narrow saw. The head of the bone is then levered out of the acetabulum. In both operations, if the acetabulum is eroded, it must be freely goug.

THE HIP-JOINT.
II. Knee-joint.

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations together: one between each condyle of the femur and the corresponding tuberosity of the tibia, which are condyloid joints, and one between the patella and the femur, which is partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals, where three synovial membranes are sometimes found, corresponding to these three subdivisions, either entirely distinct or only connected together by small communications. This view is further rendered probable by the existence of the two crucial ligaments within the joint, which must be regarded as the external and internal lateral ligaments of the inner and outer joints respectively. The existence of the ligamentum mucosum would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to each joint.

The bones entering into the formation of the knee-joint are the condyles of the femur above, the head of the tibia below, and the patella in front. The bones are connected together by ligaments, some of which are placed on the exterior of the joint, while others occupy its interior.

**External Ligaments.**
- Anterior, or Ligamentum Patellae.
- Posterior, or Ligamentum Posticum Winslowii.
- Internal Lateral.
- Two External Lateral.
- Capsular.

**Interior Ligaments.**
- Anterior, or External Crucial.
- Posterior, or Internal Crucial.
- Two Semilunar Fibro-cartilages.
- Transverse.
- Coronary.
- Ligamentum mucosum.
- Ligamenta alaria.

The **Anterior Ligament, or Ligamentum Patellae** (Fig. 257), is the central portion of the common tendon of the Extensor muscles of the thigh which is continued from the patella to the tubercle of the tibia, supplying the place of an anterior ligament. It is a strong, flat, ligamentous band about three inches in length, attached, above, to the apex of the patella and the rough depression on its posterior surface; below, to the lower part of the tubercle of the tibia, its superficial fibres being continuous over the front of the patella with those of the tendon of the Quadriceps extensor. The lateral portions of the tendon of the Extensor muscles pass down on either side of the patella, attached to the borders of this bone and its ligament, to be inserted into the upper extremity of the tibia on each side of the tubercle; externally, these portions merge into the capsular ligament. They are termed **lateral patellar ligaments**. The posterior surface of the ligamentum patellae can usually be easily separated from the front of the capsular ligament.

The **Posterior Ligament (Ligamentum Posticum Winslowii)** (Fig. 258) is a broad, flat, fibrous band formed of fasciculi, obliquely directed, and separated from another by apertures for the passage of vessels and nerves. The strongest of these fasciculi is derived from the tendon of the Semimembranosus, and passes from the back part of the inner tuberosity of the tibia obliquely upward and outward to the back part of the outer condyle of the femur, **within** the intercondyloid notch. The posterior ligament forms part of the floor of the popliteal space.

The **Internal Lateral Ligament** is a broad, flat, membranous band, thicker behind than in front, and situated nearer to the back than the front of the joint. It is attached, above, to the inner tuberosity of the femur; below, to the inner tuberosity and inner surface of the shaft of the tibia to the extent of about two inches. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis, and Semitendinosus muscles, a synovial bursa being interposed. Its **deep surface** covers the anterior portion of the tendon of the Semimembranosus, the synovial
membrane of the joint, and the inferior internal articular vessels and nerve; it is intimately adherent to the internal semilunar fibro-cartilage.

The **Long External Lateral Ligament** is a strong, rounded, fibrous cord situated nearer to the back than the front of the joint. It is attached, above, to the back part of the outer tuberosity of the femur; below, to the outer part of the head of the fibula. Its *outer surface* is covered by the tendon of the Biceps, which divides at its insertion into two parts, separated by the ligament. The ligament has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.

The **Short External Lateral Ligament** is a bundle of fibres placed behind the preceding, attached, above, together with the outer head of the Gastrocnemius, to the outer condyle of the femur; below, to the summit of the styloid process of the fibula. This ligament is intimately connected with the capsular ligament, and has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.

The **Capsular Ligament** consists of an exceedingly thin but strong, fibrous membrane which fills in the intervals left between the stronger bands above described, and is inseparably connected with them. In front it blends with the lateral patellar ligaments and fills in the interval between the anterior and lateral ligaments of the joint, with which latter structures it is closely connected. Behind, it is strong, and formed chiefly of vertical fibres, which arise above from the condyles and intercondyloid notch of the femur, and is connected below with the back part of the head of the tibia, being closely united with the origins of the Gastrocnemius, Plantaris, and Popliteus muscles. It passes in front of, but is inseparably connected with, the posterior ligament.

The **Crucial** are two interosseous ligaments of considerable strength situated...
in the interior of the joint, nearer its posterior than its anterior part. They are called crucial because they cross each other somewhat like the lines of the letter X; and have received the names anterior and posterior, from the position of their attachment to the tibia.

The Anterior, or External Crucial Ligament (Fig. 259), is attached to the depression in front of the spine of the tibia, being blended with the anterior extremity of the external semilunar fibro-cartilage, and, passing obliquely upward, backward, and outward, is inserted into the inner and back part of the outer condyle of the femur. Its direction is upward, backward, and outward.

The Posterior, or Internal Crucial Ligament, is stronger, but shorter and less oblique in its direction, than the anterior. It is attached to the back part of the depression behind the spine of the tibia, to the popliteal notch, and to the posterior extremity of the external semilunar fibro-cartilage; and passes upward, and somewhat forward, and inward, to be inserted into the outer part of the inner condyle of the femur. As it crosses the anterior crucial ligament a fasciculus is given off from it, which blends with the posterior part of that ligament. It is in relation, in front, with the anterior crucial ligament; behind, with the capsular ligament.

The Semilunar Fibro-cartilages (Fig. 260) are two crescentic lamellae which serve to deepen the surface of the head of the tibia, for articulation with the condyles of the femur. The circumference of each cartilage is thick, convex, and attached to the inside of the capsule of the knee; the inner border is thin, concave and free. Their upper surfaces are concave, and in relation with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia. Each cartilage covers nearly the outer two-thirds of the corresponding articular surface of the tibia, leaving the inner third uncovered; both surfaces are smooth and invested by synovial membrane.

The Internal Semilunar Fibro-cartilage is nearly semicircular in form, a little elongated from before backward, and broader behind than in front; its anterior extremity, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its posterior extremity is attached to the depression behind the spine, between the attachments of the external semilunar fibro-cartilage and the posterior crucial ligaments.
The External Semilunar Fibro-cartilage forms nearly an entire circle, covering a larger portion of the articular surface than the internal one. It is grooved on its outer side for the tendon of the Popliteus muscle. Its extremities, at their insertion, are interposed between the two extremities of the internal semilunar fibro-cartilage; the anterior extremity being attached in front of the spine of the tibia to the outer side of, and behind, the anterior crucial ligament, with which it blends; the posterior extremity being attached behind the spine of the tibia, in front of the posterior extremity of the internal semilunar fibro-cartilage. Just before its insertion posteriorly it gives off a strong fasciculus, which passes obliquely upward and inward, to be inserted into the inner condyle of the femur, close to the attachment of the posterior crucial ligament. Occasionally a small fasciculus is given off which passes forward to be inserted into the back part of the anterior crucial ligament. The external semilunar fibro-cartilage gives off from its anterior convex margin a fasciculus which forms the transverse ligament.

The Transverse Ligament is a band of fibres which passes transversely from the anterior convex margin of the external semilunar fibro-cartilage to the anterior convex margin of the internal semilunar fibro-cartilage; its thickness varies considerably in different subjects, and it is sometimes absent altogether.

The Coronary Ligaments are merely portions of the capsular ligament, which connect the circumference of each of the semilunar fibro-cartilages with the margin of the head of the tibia.

The Synovial Membrane of the knee-joint is the largest and most extensive in the body. Commencing at the upper border of the patella, it forms a short cul-de-sac beneath the Quadriceps extensor tendon of the thigh, on the lower part of the front of the shaft of the femur: this communicates with a synovial bursa interposed between the tendon and the front of the femur by an orifice of variable size. On each side of the patella the synovial membrane extends beneath the aponeurosis of the Vasti muscles, and more especially beneath that of the Vastus internus. Below the patella it is separated from the anterior ligament by the anterior part of the capsule and a considerable quantity of adipose-tissue. In this situation it sends off a triangular prolongation, containing a few ligamentous fibres, which extends from the anterior part of the joint below the patella to the front of the intercondyloid notch. This fold has been termed the ligamentum mucosum. It
also sends off two fringe-like folds, called the *ligamenta alaria*, which extend from the sides of the ligamentum mucosum, upward and laterally between the patella and femur. On either side of the joint it passes downward from the femur, lining the capsule to its point of attachment to the semilunar cartilages; it may then be traced over the upper surfaces of these cartilages to their free borders, and from thence along their under surfaces to the tibia. At the back part of the external one it forms a *cul-de-sac* between the groove on its surface and the tendon of the Popliteus; it surrounds the crucial ligaments and lines the inner surface of the ligaments which enclose the joints. The pouch of synovial membrane between the Extensor tendon and front of the femur is supported, during the movements of the knee, by a small muscle, the Subcrureus, which is inserted into the upper part of the capsular ligament.

The folds of synovial membrane and the fatty processes contained in them act, as it seems, mainly as padding to fill up interspaces and obviate concussions. Sometimes the bursa beneath the Quadriceps extensor is completely shut off from the rest of the synovial cavity, thus forming a closed sac between the Quadriceps and the lower part of the front of the femur, or it may communicate with the synovial cavity by a minute aperture.

The bursae about the knee-joint are the following:

In front there are three bursae: one is interposed between the patella and the skin; another, of small size, between the upper part of the tuberosity of the tibia and the ligamentum patellae; and a third between the lower part of the tuberosity of the tibia and the skin. On the outer side there are four bursae: (1) one beneath the outer head of the Gastrocnemius (which sometimes communicates with the joint); (2) one above the external lateral ligament between it and the tendon of the Biceps; (3) one beneath the external lateral ligament between it and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Popliteus between it and the condyle of the femur, which is almost always an extension from the synovial membrane.

On the inner side there are five bursae: (1) one beneath the inner head of the Gastrocnemius, which sends a prolongation between the tendons of the Gastrocnemius and Semimembranosus: this bursa often communicates with the joint; (2) one above the internal lateral ligament between it and the tendons of the Sartorius, Gracilis, and Semitendinosus; (3) one beneath the internal lateral ligament between it and the tendon of the Semimembranosus: this is sometimes only an expansion from the next bursa; (4) one beneath the tendon of the Semimembranosus, between it and the head of the tibia; (5) sometimes there is a bursa between the tendons of the Semimembranosus and of the Semitendinosus.

**Structures around the Joint.**—In front and at the sides, the Quadriceps extensor; on the outer side, the tendons of the Biceps and the Popliteus and the external popliteal nerve; on the inner side, the Sartorius, Gracilis, Semitendinosus, and Semimembranosus; behind, an expansion from the tendon of the Semimembranosus, the popliteal vessels, and the internal popliteal nerve, Popliteus, Plantaris, and inner and outer heads of the Gastrocnemius, some lymphatic glands, and fat.

The **Arteries** supplying the joint are derived from the anastomotica magna branch of the femoral, articular branches of the popliteal, anterior and posterior recurrent branches of the anterior tibial, and descending branch from the external circumflex of the Profunda.

The **Nerves** are derived from the obturator, anterior crural, and external and internal popliteal.

**Actions.**—The knee-joint permits of movements of flexion and extension, and, in certain positions, of slight rotation inward and outward. The movement of flexion and extension does not, however, take place in a simple, hinge-like manner, as in other joints, but is a complicated movement, consisting of a certain amount of gliding and rotation; so that the same part of one articular surface is not always applied to the same part of the other articular surface, and the axis
of motion is not a fixed one. If the joint is examined while in a condition of extreme flexion, the posterior part of the articular surfaces of the tibia will be found to be in contact with the posterior rounded extremities of the condyles of the femur; and if a simple hinge-like movement were to take place, the axis, round which the revolving movement of the tibia occurs, would be in the back part of the condyle. If the leg is now brought forward into a position of semiflexion, the upper surface of the tibia will be seen to glide over the condyles of the femur, so that the middle part of the articular facets are in contact, and the axis of rotation must therefore have shifted forward to nearer the centre of the condyles. If the leg is now brought into the extended position, a still further gliding takes place and a further shifting forward of the axis of rotation. This is not, however, a simple movement, but is accompanied by a certain amount of rotation outward round a vertical axis drawn through the centre of the head of the tibia. This rotation is due to the greater length of the internal condyle, and to the fact that the anterior portion of its articular surface is inclined obliquely outward. In consequence of this it will be seen that toward the close of the movement of extension—that is to say, just before complete extension is effected—the tibia glides obliquely upward and outward over this oblique surface of the inner condyle, and the leg is therefore necessarily rotated outward. In flexion of the joint the converse of these movements takes place: the tibia glides backward round the end of the femur, and at the commencement of the movement the tibia is directed downward and inward along the oblique curve of the inner condyle, thus causing an inward rotation to the leg.

During flexion and extension the patella moves on the lower end of the femur, but this movement is not a simple gliding one; for if the articular surface of this bone is examined, it will be found to present on each side of the central vertical ridge two less marked transverse ridges, which divide the surface, except a small portion along the inner border, which is cut off by a slight vertical ridge into six facets (see Fig. 262), and therefore does not present a uniform curved surface, as would be the case if a simple gliding movement took place. These six facets—three on each side of the median vertical ridge—correspond to and denote the parts of the bone respectively in contact with the condyles of the femur during flexion, semiflexion, and extension. In flexion only the upper facets on the patella are in contact with the condyles of the femur; the lower two-thirds of the bone rests upon the mass of fat which occupies the space between the femur and tibia. In the semiflexed position of the joint the middle facets on the patella rest upon the most prominent portion of the condyles, and thus afford greater leverage to the Quadriceps by increasing its distance from the centre of motion. In complete extension the patella is drawn up, so that only the lower facets are in contact with the articular surfaces of the condyles. The narrow strip along the inner border is an exception to this, and would appear to be in contact with the internal condyle throughout its whole extent in every position of the joint. As in the elbow, so it is in the knee—the axis of rotation in flexion and extension is not precisely at right angles to the axis of the bone, but during flexion there is a certain amount of alteration of plane; so that, whereas in flexion the femur and tibia are in the same plane, in extension the one bone forms an angle of about ten degrees with the other. There is, however, this difference between the two extremities: that in the upper, during extension, the humeri are parallel and the bones of the forearm diverge; in the lower, the femora converge below and the tibia are parallel.

In addition to the slight rotation during flexion and extension, the tibia enjoys an independent rotation on the condyles of the femur in certain positions of the joint. This movement takes place between the interarticular fibro-cartilages and
the tibia, whereas the movement of flexion and extension takes place between the interarticular fibro-cartilages and the femur. So that the knee may be said to consist of two joints, separated by the fibro-cartilages: an upper (menisco-femoral), in which flexion and extension take place; and a lower (menisco-tibial), allowing of a certain amount of rotation. This latter movement can only take place in the semiflexed position of the limb, when all the ligaments are relaxed.

During flexion the ligamentum patellæ is put upon the stretch, as is also the posterior crucial ligament in extreme flexion. The other ligaments are all relaxed by flexion of the joint, though the relaxation of the anterior crucial ligament is very trifling. Flexion is only checked during life by the contact of the leg with the thigh. In extension the ligamentum patellæ becomes relaxed, and, in extreme extension completely so, so as to allow free lateral movement to the patella, which then rests on the front of the lower end of the femur. The other ligaments, with the exception of the posterior crucial, which is partly relaxed, are all on the stretch. When the limb has been brought into a straight line, extension is checked mainly by the tension of all the ligaments except the posterior crucial and ligamentum patellæ. The movements of rotation, of which the knee is capable, are permitted in the semiflexed condition by the partial relaxation of both crucial ligaments, as well as the lateral ligaments. Rotation inward appears to be limited by the tension of the anterior crucial ligament, and by the interlocking of the two ligaments; but rotation outward does not appear to be checked by either crucial ligament, since they uncross during the execution of this movement, but by the lateral ligaments, especially the internal. The main function of the cruciate ligaments is to act as a direct bond of union between the tibia and femur, preventing the former bone from being carried too far backward or forward. Thus the anterior crucial ligament prevents the tibia being carried too far forward by the extensor tendons, and the posterior crucial checks too great movement backward by the flexors. They also assist the lateral ligaments in resisting any lateral bending of the joint. The interarticular cartilages are intended, as it seems, to adapt the surface of the tibia to the shape of the femur to a certain extent, so as to fill up the intervals which would otherwise be left in the varying positions of the joint, and to interrupt the jars which would be so frequently transmitted up the limb in jumping or falls on the feet; also to permit of the two varieties of motion, flexion and extension, and rotation, as explained above. The patella is a great defence to the knee-joint from any injury inflicted in front, and it distributes upon a large and tolerably even surface during kneeling the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps extensor muscle to act upon the tibia; and Mr. Ward has pointed out how this leverage varies in the various positions of the joint, so that the action of the muscles produces velocity at the expense of force in the commencement of extension, and, on the contrary, at the close of extension tends to diminish velocity, and therefore the shock to the ligaments; whilst in the standing position it draws the tibia powerfully forward, and thus maintains it in its place.

Extension of the leg on the thigh is performed by the Quadriceps extensor; flexion by the hamstring muscles, assisted by the Gracilis and Sartorius, and, indirectly, by the Gastrocnemius, Popliteus, and Plantaris; rotation outward, by the Biceps; and rotation inward by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis.

Surface Form.—The interval between the two bones entering into the formation of the knee-joint can always easily be felt. If the limb is extended, it is situated on a slightly higher level than the apex of the patella; but if the limb is slightly flexed, a knife carried horizontally backward immediately below the apex of the patella would pass directly into the joint. When the knee-joint is distended with fluid, the outline of the synovial membrane at the front of the knee may be fairly well mapped out.

Surgical Anatomy.—From a consideration of the construction of the knee-joint it would at first sight appear to be one of the least secure of any of the joints in the body. It is formed

1 Human Osteology, p. 405.
THE KNEE-JOINT.

375

between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is very considerable; the articular surfaces are but ill adapted to each other, and the range and variety of motion which it enjoys is great. All these circumstances tend to render the articulation very insecure; but, nevertheless, on account of the very powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from trauma is of very rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is very liable to occur, and is frequently brought about by the mere action of the muscles displacing the articular surfaces from each other. The tibia may be dislocated in any direction from the femur—forward, backward, inward, or outward; or a combination of two of these dislocations may occur—that is, the tibia may be dislocated forward and laterally, or backward and laterally; and any of these dislocations may be complete or incomplete. As a rule, however, the antero-posterior dislocations are complete, while the lateral ones incomplete.

One or other of the semilunar cartilages may become displaced and pressed between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The cartilage may be displaced either inward or outward; that is to say, either inward toward the tibial spine, so that the cartilage becomes lodged in the intercondylar notch; or outward, so that the cartilage projects beyond the margin of the two articulating bones. Acute synovitis, the result of trauma or exposure to cold, is very common in the knee, on account of its superficial position. When distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about an inch or more above the trochlear surface of the femur, and extending a little higher under the Vastus internus than the Vastus externus. Occasionally the swelling may extend two inches or more. At the sides of the patella the swelling extends lower at the inner side than it does on the outer side. The lower level of the synovial membrane is just above the level of the upper part of the head of the fibula. In the middle line it covers the upper third of the ligamentum patellae, being separated from it, however, by the capsule and a little fat. Chronic synovitis principally shows itself in the form of pulp degeneration of the synovial membrane, leading to tubercular arthritis. The reasons why tubercular disease of the knee usually commences in the synovial membrane appear to be the complex and extensive nature of this sac; the extensive vascular supply to it; and the fact that injuries are generally diffused and applied to the front of the joint rather than to the ends of the bones. Syphilitic disease not infrequently attacks the knee-joint. In the hereditary form of the disease it is usually symmetrical, attacking both joints, which become filled with synovial effusion, and is very intractable and difficult of cure. In the tertiary form of the disease gummatous infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with osteo-arthritis, and is said to be more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilage is almost confined to the knee, though they are occasionally met with in the elbow, and, rarely, in some other joints. Many of them occur in cases of osteo-arthritis, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only merit the usual term, "loose" cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the semilunar cartilages becomes detached and constitutes the foreign body.

Genu valgum, or knock-knee, is a common deformity of childhood, in which, owing to changes in and about the joint, the angle between the outer border of the tibia and femur is diminished, so that as the patient stands the two internal condyles of the femora are in contact, but the two internal malleoli of the tibiae are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the internal lateral ligament and other fibrous structures on the inner side of the joint; as a result of this there is a constant undue pressure of the outer tuberosity of the tibia against the outer condyle of the femur. This extra pressure causes arrest of growth and, possibly, wasting of the outer condyle, and a consequent tendency for the tibia to become separated from the internal condyle. To prevent this the internal condyle becomes depressed; probably, as was first pointed out by Mikulicz, by an increased growth of the lower end of the diaphysis on its inner side, so that the line of the epiphysis becomes oblique instead of transverse to the axis of the bone, with a direction downward and inward.

Excision of the knee-joint is most frequently required for tubercular disease of this articulation, but is also practised in cases of disorganization of the knee after rheumatic fever, pyaemia, etc., in osteo-arthritis, and in ankylosis. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed either by a horseshoe incision, starting from one condyle, descending as low as the tubercle of the tibia, where it crosses the leg; and is then carried upward to the other condyle; or by a transverse incision across the patella. In this latter incision the patella is either removed or sawn across, and the halves subsequently sutured together. The bones being having been cleared, and in those cases where the operation is performed for tubercular disease all pulp tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphysis will be included, with disastrous results as far as regards the growth of the limb. Afterward a thin slice should be removed from the upper
end of the tibia, not more than half an inch. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge rather than that a further section of the bones
should be made.

III. Articulations between the Tibia and Fibula.

The articulations between the tibia and fibula are effected by ligaments which connect both extremities, as well as the shafts of the bones. They may, consequently, be subdivided into three sets: 1. The Superior Tibio-fibular articulation. 2. The Middle Tibio-fibular ligament or interosseous membrane. 3. The Inferior Tibio-fibular articulation.

1. Superior Tibio-fibular Articulation.

This articulation is an arthrodiol joint. The contiguous surfaces of the bones present two flat, oval facets covered with cartilage, and connected together by the following ligaments:

Anterior Superior Tibio-fibular.
Posterior Superior Tibio-fibular.

The Anterior Superior Ligament (Fig. 259) consists of two or three broad and flat bands which pass obliquely upward and inward from the front of the head of the fibula to the front of the outer tuberosity of the tibia.
The Posterior Superior Ligament (Fig. 258) is a single thick and broad band which passes upward and inward from the back part of the head of the fibula to the back part of the outer tuberosity of the tibia. It is covered by the tendon of the Popliteus muscle.
A Synovial Membrane lines this articulation, which at its upper and back part is occasionally continuous with that of the knee-joint.

2. Middle Tibio-fibular Ligament or Interosseous Membrane.

An interosseous membrane extends between the contiguous margins of the tibia and fibula, and separates the muscles on the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres which pass downward and outward between the interosseous ridges on the two bones. It is broader above than below. Above its upper border is a large, oval aperture for the passage of the anterior tibial vessels forward to the anterior aspect of the leg; and at its lower part an opening for the passage of the anterior peroneal vessels. It is continuous below with the inferior interosseous ligament, and is perforated in numerous parts for the passage of small vessels. It is in relation, in front, with the Tibialis anticus, Extensor longus digitorum, Extensor proprius hallucis, Peroneus tertius, and the anterior tibial vessels and nerve; behind, with the Tibialis posticus and Flexor longus hallucis.

3. Inferior Tibio-fibular Articulation.

This articulation is formed by the rough, convex surface of the inner side of the lower end of the fibula, connected with a concave rough surface on the outer side of the tibia. Below, to the extent of about two lines, these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments of this joint are—

Anterior Inferior Tibio-fibular. Transverse.
Posterior Inferior Tibio-fibular. Inferior Interosseous.

The Anterior Inferior Ligament (Fig. 264) is a flat, triangular band of fibres, broader below than above, which extends obliquely downward and outward between the adjacent margins of the tibia and fibula, on the front aspect of the articulation. It is in relation, in front, with the Peroneus tertius, the aponeurosis
of the leg, and the integument; behind, with the inferior interosseous ligament; and lies in contact with the cartilage covering the astragalus.

The Posterior Inferior Ligament, smaller than the preceding, is disposed in a similar manner on the posterior surface of the articulation.

The Transverse Ligament is a long, narrow band, continuous with the preceding, passing transversely across the back of the joint, from the external malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the astragalus.

The Inferior Interosseous Ligament consists of numerous short, strong, fibrous bands which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. This ligament is continuous above with the interosseous membrane.

The Synovial Membrane lining the articular surface is derived from that of the ankle-joint.

Actions.—The movement permitted in these articulations is limited to a very slight gliding of the articular surfaces one upon another.

IV. Ankle-joint.

The Ankle is a ginglymus or hinge-joint. The bones entering into its formation are the lower extremity of the tibia and its malleolus and the external malleolus of the fibula. These bones are united above, and form a mortise to receive the upper convex surface of the astragalus and its two lateral facets. The bony surfaces are covered with cartilage, and connected together by a capsule, which in places forms thickened bands constituting the following ligaments:

Anterior. Internal Lateral.
Posterior. External Lateral.

The Anterior Tibio-tarsal Ligament (Fig. 263) is a broad, thin, membranous layer, attached, above, to the margin of the articular surface of the tibia; below,
anticus and Peroneus tertius, and the anterior tibial vessels and nerve; behind, it lies in contact with the synovial membrane.

The **Posterior Tibio-tarsal Ligament** is very thin, and consists principally of transverse fibres. It is attached, above, to the margin of the articular surface of the tibia, blending with the transverse tibio-fibular ligament; below, to the astragalus, behind its superior articular facet. Externally it is thicker than internally, where a somewhat thickened band of transverse fibres is attached to the hollow on the inner surface of the external malleolus.

The **Internal Lateral or Deltoid Ligament** is a strong, flat, triangular band, attached, above, to the apex and anterior and posterior borders of the internal malleolus. The most anterior fibres pass forward to be inserted into the navicular bone and the inferior calcaneo-navicular ligament; the middle descend almost perpendicularly to be inserted into the sustentaculum tali of the os calcis; and the posterior fibres pass backward and outward to be attached to the inner side of the astragalus. This ligament is covered by the tendons of the Tibialis posticus and Flexor longus digitorum muscles.

The **External Lateral Ligament** (Fig. 264) consists of three distinctly specialized fasciculi of the capsule, taking different directions and separated by distinct intervals; for which reason it is described by some anatomists as three distinct ligaments.¹

The **anterior fasciculus** (anterior astragalo-fibular), the shortest of the three, passes from the anterior margin of the summit of the external malleolus, downward and forward, to the astragalus, in front of its external articular facet.

The **posterior fasciculus** (posterior astragalo-fibular), the most deeply seated, passes from the depression at the inner and back part of the external malleolus to a prominent tubercle on the posterior surface of the astragalus. Its fibres are almost horizontal in direction.

The **middle fasciculus** (calcaneo-fibular), the longest of the three, is a narrow, rounded cord passing from the apex of the external malleolus downward and slightly backward to a tubercle on the outer surface of the os calcis. It is covered by the tendons of the Peroneus longus and brevis.

THE ANKLE-JOINT.

The Synovial Membrane invests the inner surface of the ligaments, and sends a duplicature upward between the lower extremities of the tibia and fibula for a short distance.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in front, from within outward, the Tibialis anticus, Extensor proprius hallucis, anterior tibial vessels, anterior tibial nerve, Extensor communis digitorum, and Peroneus tertius; behind, from within outward, the Tibialis posticus, Flexor longus digitorum, posterior tibial vessels, posterior tibial nerve, Flexor longus hallucis; and, in the groove below the external malleolus, the tendons of the Peroneus longus and brevis.

The Arteries supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.

The Nerves are derived from the anterior and posterior tibial.

Actions.—The movements of the joint are those of flexion and extension. The malleoli tightly embrace the astragalus in all positions of the joint, so that any slight degree of lateral movement which may exist is simply due to stretching of the inferior tibio-fibular ligaments and slight bending of the shaft of the fibula. Of the ligaments, the internal, or deltoid, is of very great power—so much so that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the middle fasciculus of the external lateral ligament, binds the bones of the leg firmly to the foot and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior portion of the external lateral ligament assists the middle portion in resisting the displacement of the foot backward, and deepens the cavity for the reception of the astragalus. The anterior fasciculus is a security against the displacement of the foot forward, and limits extension of the joint. The movements of abduction and adduction of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, etc., are mainly effected in the tarsal joints, the one which enjoys the greatest amount of motion being that between the astragalus and os calcis behind and the navicular and cuboid in front. This is often called the transverse or medio-tarsal joint, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the tarsal bones upon the tibia and fibula is produced by the Gastrocnemius. Soleus, Plantaris, Tibialis posterior, Peroneus longus and brevis, Flexor longus digitorum, and Flexor longus hallucis; flexion, by the Tibialis anticus, Peroneus tertius, Extensor longus digitorum, and Extensor proprius hallucis; adduction, in the extended position, is produced by the Tibialis anticus and posticus; and abduction by the Peronei.

Surface Form.—The line of the ankle-joint may be indicated by a transverse line drawn across the front of the lower part of the leg, about half an inch above the level of the tip of the internal malleolus.

Surgical Anatomy.—Displacement of the trochlear surface of the astragalus from the tibio-fibular mortise is not of common occurrence, as the ankle-joint is a very strong and powerful articulation, and great force is required to produce it. Nevertheless, dislocation does occasionally occur, both in an antero-posterior and a lateral direction. In the latter, which is the most common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontally lateral direction, such as usually occurs in lateral dislocations of ginglymoid joints, but the astragalus undergoes a partial rotation round an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upward, is inclined more or less inward or outward according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the Tibialis anticus and the internal lateral ligament on the inner side, and between the

1 The student must bear in mind that the Extensor longus digitorum and Extensor proprius hallucis are extensors of the toes, but flexors of the ankle, and that the Flexor longus digitorum and Flexor longus hallucis are flexors of the toes, but extensors of the ankle.
Peroneus tertius and the external lateral ligament on the outer side. In addition to this, bulging frequently occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo Achillis.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is more liable to a recurrence of the injury than it was before; or it may be tubercular in its origin, the disease usually commencing in the astragalus and extending to the joint, though it may commence as a tubercular synovitis the result probably of some slight strain in a tubercular subject.

Excision of the ankle-joint is not often performed for two reasons. In the first place, disease of the articular for which this operation is indicated is frequently associated with disease of the tarsal bones, which prevents its performance; and, secondly, the foot after excision is frequently of very little use; far less, in fact, than after a Symes’s amputation, which is often, therefore, a preferable operation in these cases. Excision may, however, be attempted in cases of tubercular arthritis, in a young and otherwise healthy subject, where the disease is limited to the bones forming the joint. It may also be required after injury where the vessels and nerves have not been damaged and the patient is young and free from visceral disease. The excision is best performed by two lateral incisions. One commencing two and a half inches above the external malleolus, carried down the posterior border of the fibula, round the end of the bone, and then forward and downward as far as the calcaneo-cuboid joint, midway between the tip of the external malleolus and the tuberosity on the fifth metatarsal bone. Through this incision the fibula is cleared, the external lateral ligament is divided, and the bone sawn through at the upper end of the incision and removed. A similar curved incision is now made on the inner side of the foot, commencing two and a half inches above the lower end of the tibia, carried down the posterior border of the bone, round the internal malleolus, and forward and downward to the tuberosity of the navicular bone. Through this incision the tibia is cleared in front and behind, the internal lateral, the anterior and posterior ligaments divided, and the end of the tibia protruded through the wound by displacing the foot outward, and sawn off sufficiently high to secure a healthy section of bone. The articular surface of the astragalus is now to be sawn off or the whole bone removed. In cases where the operation is performed for tubercular arthritis the latter course is probably preferable, as the injury done by the saw is frequently the starting point of fresh caries; and after removal of the whole bone the shortening is not appreciably increased, and the result as regards union appears to be as good as when two sawn surfaces of bone are brought into apposition.

V. Articulations of the Tarsus.

1. Articulations of the Os Calcis and Astragalus.

The articulations between the os calcis and astragalus are two in number—anterior and posterior. They are arthrodial joints. The bones are connected together by four ligaments:

- External Calcaneo-astragaloid.
- Internal Calcaneo-astragaloid.
- Posterior Calcaneo-astragaloid.
- Interosseous.
The External Calcaneo-astragaloid Ligament (Fig. 264) is a short, strong, fasciculus passing from the outer surface of the astragalus; immediately beneath its external malleolar facet, to the outer surface of the os calcis. It is placed in front of the middle fasciculus of the external lateral ligament of the ankle-joint, with the fibres of which it is parallel.

The Internal Calcaneo-astragaloid Ligament is a band of fibres connecting the internal tubercle of the back of the astragalus with the back of the sustentaculum tali. Its fibres blend with those of the inferior calcaneo-navicular ligament.

The Posterior Calcaneo-astragaloid Ligament (Fig. 263) connects the posterior external tubercle of the astragalus with the upper and inner part of the os calcis; it is a short, narrow band, the fibres of which radiate from their narrow attachment to the astragalus:

The Interosseous Ligament forms the chief bond of union between the bones. It consists of numerous vertical and oblique fibres attached by one extremity to the groove between the articulating facets on the under surface of the astragalus; by the other to a corresponding depression on the upper surface of the os calcis. It is very thick and strong, being at least an inch in breadth from side to side, and serves to unite the os calcis and astragalus solidly together.

The Synovial Membranes (Fig. 267) are two in number: one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid joint. The latter synovial membrane is continued forward between the contiguous surfaces of the astragalus and navicular bones.

Actions.—The movements permitted between the astragalus and os calcis are limited to a gliding of the one bone on the other in a direction from behind forward, and from side to side.

2. Articulations of the Os Calcis with the Cuboid.

The ligaments connecting the os calcis with the cuboid are four in number:

Dorsal.  { Superior Calcaneo-cuboid.
          { Internal Calcaneo-cuboid (Interosseous).

Plantar.  { Long Calcaneo-cuboid.
          { Short Calcaneo-cuboid.

The Superior Calcaneo-cuboid Ligament (Fig. 264) is a thin and narrow fasciculus which passes between the contiguous surfaces of the os calcis and cuboid on the dorsal surface of the joint.

The Internal Calcaneo-cuboid (Interosseous) Ligament (Fig. 264) is a short but thick and strong band of fibres arising from the os calcis, in the deep hollow which intervenes between it and the astragalus, and closely blended, at its origin, with the superior calcaneo-navicular ligament. It is inserted into the inner side of the cuboid bone. This ligament forms one of the chief bonds of union between the first and second rows of the tarsus.

The Long Calcaneo-cuboid (Long Plantar) Ligament (Fig. 266), the more superficial of the two plantar ligaments, is the longest of all the ligaments of the tarsus: it is attached to the under surface of the os calcis, from near the tuberosities, as far forward as the anterior tubercle; its fibres pass forward to be attached to the ridge on the under surface of the cuboid bone, the more superficial fibres being continued onward to the bases of the second, third, and fourth metatarsal bones. This ligament crosses the groove on the under surface of the cuboid bone, converting it into a canal for the passage of the tendon of the Peroneus longus.

The Short Calcaneo-cuboid (Short Plantar) Ligament lies nearer to the bones than the preceding, from which it is separated by a little adipose tissue. It is exceedingly broad, about an inch in length, and extends from the tubercle and the depression in front of it, on the fore part of the under surface of the os calcis, to the inferior surface of the cuboid bone behind the peroneal groove.
Synovial Membrane.—The synovial membrane in this joint is distinct. It lines the inner surface of the ligaments.

Actions.—The movements permitted between the os calcis and cuboid are limited to a slight gliding upon each other.

3. The Ligaments connecting the Os Calcis and Navicular.

Though these two bones do not directly articulate, they are connected together by two ligaments:

Superior or External Calcaneo-navicular.
Inferior or Internal Calcaneo-navicular.

The Superior or External Calcaneo-navicular (Fig. 264) arises, as already mentioned, with the internal calcaneo-cuboid in the deep hollow between the astragalus and os calcis; it passes forward from the inner side of the anterior extremity of the os calcis to the outer side of the navicular bone. These two ligaments resemble the letter Y, being blended together behind, but separated in front.

The Inferior or Internal Calcaneo-navicular (Fig. 266) is by far the larger and stronger of the two ligaments between these bones; it is a broad and thick band of fibres, which passes forward and inward from the anterior margin of the sustentaculum tali of the os calcis to the under surface of the navicular bone. This ligament not only serves to connect the os calcis and navicular, but supports the head of the astragalus, forming part of the articular cavity in which it is received. The upper surface presents a fibro-cartilaginous facet, lined by the synovial membrane continued from the anterior calcaneo-astragaloid articulation, upon which the head of the astragalus rests. Its under surface is in contact with the tendon of the Tibialis posticus muscle; its inner border is blended with the fore part of the Deltoid ligament, thus completing the socket for the head of the astragalus.

Surgical Anatomy.—The inferior calcaneo-navicular ligament, by supporting the head of the astragalus, is principally concerned in maintaining the arch of the foot, and when it yields the head of the astragalus is pressed downward, inward, and forward by the weight of the body, and the foot becomes flattened, expanded, and turned outward, constituting the disease known as flat-foot. This ligament contains a considerable amount of elastic fibre, so as to give elasticity to the arch and spring to the foot; hence it is sometimes called the “spring” ligament. It is supported, on its under surface, by the tendon of the Tibialis posticus, which spreads out at its insertion into a number of fasciculi which are attached to most of the tarsal and metatarsal bones; this prevents undue stretching of the ligament and is a protection against the occurrence of flat-foot.

4. Articulation of the Astragalus with the Navicular Bone.

The articulation between the astragalus and navicular is an arthrodial joint: the rounded head of the astragalus being received into the concavity formed by

1 Mr. Hancock describes an extension of this ligament upward on the inner side of the foot, which completes the socket of the joint in that direction (Lancet, 1866, vol. i. p. 618).
the posterior surface of the navicular, the anterior articulating surface of the calcaneum, and the upper surface of the inferior calcaneo-navicular ligament, which fills up the triangular interval between those bones. The only ligament of this joint is the superior astragalo-navicular. It is a broad band, which passes obliquely forward from the neck of the astragalus to the superior surface of the navicular bone. It is thin, and weak in texture, and covered by the Extensor tendons. The inferior calcaneo-navicular supplies the place of an inferior ligament.

The Synovial Membrane which lines the joint is continued forward from the anterior calcaneo-astragaloid articulation.

Actions.—This articulation permits of considerable mobility, but its feebleness is such as to allow occasionally of dislocation of the other bones of the tarsus from the astragalus.

The transverse tarsal or medio-tarsal joint is formed by the articulation of the os calcis with the cuboid, and by the articulation of the astragalus with the navicular. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the sole of the foot may be slightly flexed and extended or carried inward and outward.

5. The Articulation of the Navicular with the Cuneiform Bones.

The navicular is connected to the three cuneiform bones by Dorsal and Plantar ligaments.

The Dorsal Ligaments are small, longitudinal bands of fibrous tissue arranged as three bundles, one to each of the cuneiform bones. That bundle of fibres which connects the navicular with the internal cuneiform is continued round the inner side of the articulation to be continuous with the plantar ligament which connects these two bones.

The Plantar Ligaments have a similar arrangement to those on the dorsum. They are strengthened by processes given off from the tendon of the Tibialis posticus.

Actions.—The movements permitted between the navicular and cuneiform bones are limited to a slight gliding upon each other.

The Synovial Membrane of these joints is part of the great tarsal synovial membrane.

6. The Articulation of the Navicular with the Cuboid.

The navicular bone is connected with the cuboid by Dorsal, Plantar, and Interosseous ligaments.

The Dorsal Ligament consists of a band of fibrous tissue which passes obliquely forward and outward from the navicular to the cuboid bone.

The Plantar Ligament consists of a band of fibrous tissue which passes nearly transversely between these two bones.

The Interosseous Ligament consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of these two bones.

Actions.—The movements permitted between the navicular and cuboid bones are limited to a slight gliding upon each other.

The Synovial Membrane of this joint is part of the great tarsal synovial membrane.

7. The Articulation of the Cuneiform Bones with Each Other.

These bones are connected together by Dorsal, Plantar, and Interosseous ligaments.

The Dorsal Ligaments consist of two bands of fibrous tissue which pass transversely, one connecting the internal with the middle cuneiform, and the other connecting the middle with the external cuneiform.

The Plantar Ligaments have a similar arrangement to those on the dorsum.
They are strengthened by the processes given off from the tendon of the Tibialis posticus.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent cuneiform bones.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

**Actions.**—The movements permitted between the cuneiform bones are limited to a slight gliding upon each other.

8. **THE Articulation of the External Cuneiform Bone with the Cuboid.**

These bones are connected together by

Dorsal, Planter, and Interosseous ligaments.

The **Dorsal Ligament** consists of a band of fibrous tissue which passes transversely between these two bones.

The **Planter Ligament** has a similar arrangement. It is strengthened by a process given off from the tendon of the Tibialis posticus.

The **Interosseous Ligament** consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent sides of these two bones.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

**Actions.**—The movements permitted between the external cuneiform and cuboid are limited to a slight gliding upon each other.

**Nerve-supply.**—All the joints of the tarsus are supplied by the anterior tibial nerve.

**Surgical Anatomy.**—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur; though, on account of the spongy character of the bones, they are more frequently broken than dislocated, as the result of violence. When dislocation does occur, it is most commonly in connection with the astragalus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the trochlear surface of the bone remaining in situ in the tibio-fibular mortise. This constitutes what is known as the *subastragaloïd* dislocation. Or, again, the astragalus may be dislocated from all its connections—from the tibia and fibula above, the os calcis below, and the navicular in front—and may even undergo a rotation, either on a vertical or horizontal axis. In the former case the long axis of the bone becoming directed across the joint, so that the head faces the articular surface on one or other malleolus; or, in the latter, the lateral surfaces becoming directed upward and downward, so that the trochlear surface faces to one or the other side. Finally, dislocation may occur at the medio-tarsal joint, the anterior tarsal bones being luxated from the astragalus and calcaneum. The other tarsal bones are also, occasionally, though rarely, dislocated from their connections.

VI. **Tarso-metatarsal Articulations.**

These are arthrodial joints. The bones entering into their formation are four tarsal bones—viz. the internal, middle, and external cuneiform and the cuboid—which articulate with the metatarsal bones of the five toes. The metatarsal bone of the great toe articulates with the internal cuneiform; that of the second is deeply wedged in between the internal and external cuneiform, resting against the middle cuneiform, and being the most strongly articulated of all the metatarsal bones; the third metatarsal articulates with the extremity of the external cuneiform; the fourth with the cuboid and external cuneiform; and the fifth, with the cuboid. The articular surfaces are covered with cartilage, lined by synovial membrane, and connected together by the following ligaments:

Dorsal.  Plantar.  Interosseous.

The **Dorsal Ligaments** consist of strong, flat, fibrous bands, which connect the tarsal with the metatarsal bones. The first metatarsal is connected to the internal cuneiform by a single broad, thin, fibrous band; the second has three dorsal
ligaments, one from each cuneiform bone; the third has one from the external cuneiform; the fourth has two, one from the external cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The Plantar Ligaments consist of longitudinal and oblique fibrous bands connecting the tarsal and metatarsal bones, but disposed with less regularity than on the dorsal surface. Those for the first and second metatarsal are the most strongly marked; the second and third metatarsal receive strong fibrous bands which pass obliquely across from the internal cuneiform; the plantar ligaments of the fourth and fifth metatarsal consist of a few scanty fibres derived from the cuboid.

The Interosseous Ligaments are three in number—internal, middle, and external. The internal one passes from the outer extremity of the internal cuneiform to the adjacent angle of the second metatarsal. The middle one, less strong than the preceding, connects the external cuneiform with the adjacent angle of the second metatarsal. The external interosseous ligament connects the outer angle of the external cuneiform with the adjacent side of the third metatarsal.

The Synovial Membrane between the internal cuneiform bone and the first metatarsal bone is a distinct sac. The synovial membrane between the middle and external cuneiform behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forward from it—one between the adjacent sides of the second and third metatarsal bones, and one between the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones is a distinct sac. From it a prolongation is sent forward between the fourth and fifth metatarsal bones.

Actions.—The movements permitted between the tarsal and metatarsal bones are limited to a slight gliding upon each other.

Articulations of the Metatarsal Bones with Each Other.

The base of the first metatarsal bone is not connected with the second metatarsal bone by any ligaments; but there may be a bursa between the "occasional" facets (see page 307).

The bases of the four outer metatarsal bones are connected together by dorsal, plantar, and interosseous ligaments.

The Dorsal Ligaments consist of bands of fibrous tissue which pass transversely between the adjacent metatarsal bones.

The Plantar Ligaments have a similar arrangement to those on the dorsum.

The Interosseous Ligaments consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces.

The Synovial Membrane between the second and third and the third and fourth metatarsal bones is part of the great tarsal synovial membrane.

The synovial membrane between the fourth and fifth metatarsal bones is a prolongation of the synovial membrane of the cubo-metatarsal joint.

Actions.—The movement permitted in the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another.

The Synovial Membranes in the Tarsal and Metatarsal Joints.

The Synovial Membranes (Fig. 267) found in the articulations of the tarsus and metatarsus are six in number: one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid and astragalal-navicular articulations; a third for the calcaneo-cuboid articulation; and a fourth for the articulations of the navicular with the three cuneiform, the three cuneiform with each other, the external cuneiform with the cuboid, and the middle and external cuneiform with the bases of the second and third metatarsal bones, and the lateral surfaces of the second, third, and fourth metatarsal bones with each other; a fifth for the internal cuneiform with the metatarsal bone of the great toe; and a sixth for the articulation of the cuboid with the fourth and fifth metatarsal bones. A
small synovial membrane is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

**Nerve-supply.**—The nerves supplying the tarso-metatarsal joints are derived from the anterior tibial.

The *digital extremities* of all the metatarsal bones are connected together by the transverse metatarsal ligament.

The Transverse Metatarsal Ligament is a narrow fibrous band which passes transversely across the anterior extremities of all the metatarsal bones, connecting them together. It is blended anteriorly with the plantar (glenoid) ligament of the metatarso-phalangeal articulations. To its posterior border is connected the fascia covering the Interossei muscles. Its superficial surface is concave where the Flexor tendons pass over it. Beneath it the tendons of the Interossei muscles pass to their insertion. It differs from the transverse metacarpal ligament in that it connects the metatarsal bone of the great toe with the rest of the metatarsal bones.

**VII. Metatarso-phalangeal Articulations.**

The metatarso-phalangeal articulations are of the condyloid kind, formed by the reception of the rounded head of the metatarsal bone into a superficial cavity in the extremity of the first phalanx.

The ligaments are—

Plantar. Two Lateral.

The **Plantar Ligaments** (Glenoid ligaments of Cruveilhier) are thick, dense, fibrous structures. Each is placed on the plantar surface of the joint in the interval between the lateral ligaments, to which they are connected; they are loosely united to the metatarsal bone, but very firmly to the base of the first phalanges. Their plantar surface is intimately blended with the transverse metatarsal ligament, and presents a groove for the passage of the Flexor tendons, the sheath surrounding which is connected to each side of the groove. By their deep surface they form part of the articular surface for the head of the metatarsal bone, and are lined by a synovial membrane.

The **Lateral Ligaments** are strong, rounded cords, placed one on each side of the joint, each being attached, by one extremity, to the posterior tubercle on the side of the head of the metatarsal bone; and, by the other, to the contiguous extremity of the phalanx.

The **Posterior Ligament** is supplied by the extensor tendon placed over the back of the joint.

**Actions.**—The movements permitted in the metatarso-phalangeal articulations are flexion, extension, abduction, and adduction.

![Oblique section of the articulations of the tarsus and metatarsus. Showing the six synovial membranes.](image)
OF THE PHALANGES.

VIII. Articulations of the Phalanges.
The articulations of the phalanges are ginglymus joints.
The ligaments are—

**Plantar.**

**Two Lateral.**

The arrangement of these ligaments is similar to those in the metatarso-phalangeal articulations; the extensor tendon supplies the place of a posterior ligament.

**Actions.**—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

**Surface Form.**—The principal joints which it is necessary to distinguish, with regard to the surgery of the foot, are the medio-tarsal and the tarso-metatarsal joints. The joint between the astragalus and the navicular is best found by means of the tubercle of the navicular bone, for the line of the joint is immediately behind this process. If the foot is grasped and forcibly extended, a rounded prominence, the head of the astragalus, will appear on the inner side of the dorsum in front of the ankle-joint, and if a knife is carried downward, just in front of this prominence and behind the line of the navicular tubercle, it will enter the astragalo-navicular joint. The calcaneo-cuboid joint is situated midway between the external malleolus and the prominent end of the fifth metatarsal bone. The plane of the joint is in the same line as that of the astragalo-navicular. The position of the joint between the fifth metatarsal bone and the cuboid is easily found by the projection of the fifth metatarsal bone, which is the guide to it. The direction of the line of the joint is very oblique, so that, if continued onward, it would pass through the head of the first metatarsal bone. The joint between the fourth metatarsal bone and the cuboid and external cuneiform is the direct continuation inward of the previous joint, but its plane is less oblique; it would be represented by a line drawn from the outer side of the articulation to the middle of the first metatarsal bone. The plane of the joint between the third metatarsal bone and the external cuneiform is almost transverse. It would be represented by a line drawn from the outer side of the joint to the base of the first metatarsal bone. The tarse-metatarsal articulation of the great toe corresponds to a groove which can be felt by making firm pressure on the inner side of the foot one inch in front of the tubercle on the navicular bone; and the joint between the second metatarsal bone and the middle cuneiform is to be found on the dorsum of the foot, half an inch behind the level of the tarso-metatarsal joint of the great toe. The line of the joints between the metatarsal bones and the first phalanges is about an inch behind the webs of the corresponding toes.
THE MUSCLES AND FASCIAE.

The muscles are connected with the bones, cartilages, ligaments, and skin, either directly or through the intervention of fibrous structures called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres terminate in blunt extremities upon the periosteaum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they either lie as a flattened layer beneath it, or are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face.

The muscles vary extremely in their form. In the limbs, they are of considerable length, especially the more superficial ones, the deep ones being generally broad; they surround the bones and form an important protection to the various joints. In the trunk they are broad, flattened, and expanded, forming the parietes of the cavities which they enclose; hence the reason of the terms, long, broad, short, etc., used in the description of a muscle.

There is a considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some, the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyro-hyoid. A modification of these is found in the fusiform muscles, in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at each end; in their action, however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the triangular muscles—e.g., the Temporal. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line of origin intersects that of their insertion; such is the case in the Pectineus muscle.

Thirdly, in some muscles the fibres are oblique and converge, like the plumes of a pen, to one side of a tendon, which runs the entire length of the muscle. Such a muscle is rhomboidal or penniform, as the Peronei. A modification of these rhomboidal muscles is found in those cases where oblique fibres converge to both sides of a central tendon which runs down the middle of the muscle; these are called bipenniform, and an example is afforded in the Rectus femoris. Finally, we have muscles in which the fibres are arranged in curved bundles in one or more planes, as in the Sphincter muscles. The arrangement of the muscular fibres is of considerable importance in respect to their relative strength and range of movement. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

Muscles differ much in size: the Gastrocnemius forms the chief bulk of the back of the leg, and the fibres of the Sartorius are nearly two feet in length, whilst

1 The Muscles and Fascia are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciae separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the anatomy of the muscles and fasciae, the special description being given in connection with the different regions.
the Stapedius, a small muscle of the internal ear, weighs about a grain, and its fibres are not more than two lines in length.

The names applied to the various muscles have been derived—1, from their situation, as the Tibialis, Radialis, Ulnaris, Peroneus; 2, from their direction, as the Rectus abdominis, Obliqui capitis, Transversalis; 3, from their uses, as Flexors, Extensors. Abductors, etc.; 4, from their shape, as the Deltoid, Trapezius, Rhomboidens; 5, from the number of their divisions, as the Biceps, the Triceps; 6, from their points of attachment, as the Sterno-cleido-mastoid, Sterno-hyoid, Sterno-thyroid.

In the description of a muscle the term origin is meant to imply its more fixed or central attachment, and the term insertion, the movable point to which the force of the muscle is directed; but the origin is absolutely fixed in only a very small number of muscles, such as those of the face, which are attached by one extremity to the bone and by the other to the movable integument; in the greater number the muscle can be made to act from either extremity.

In the dissection of the muscles the student should pay especial attention to the exact origin, insertion, and actions of each, and its more important relations with surrounding parts. An accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their action. By a knowledge of the action of the muscles the surgeon is able to explain the causes of displacement in various forms of fracture and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger blood-vessels, and the surface-markings they produce, should be especially remembered, as they form useful guides in the application of a ligature to those vessels.

Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, of considerable strength, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons presenting in their interior not a trace of them. Nerves also are not present in the smaller tendons, but the larger ones, as the tendo Achillis, receive nerves which accompany the nutrient vessels. The tendons consist principally of a substance which yields gelatin.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white color, iridescent, glistening, and similar in structure to the tendons. They are destitute of nerves, and the thicker ones only sparingly supplied with blood-vessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles, and, on the other hand, with the movable structures, as the bones, cartilages, ligaments, fibrous membranes (for instance, the sclerotic), and the synovial membranes (subcruereus). Where the muscular fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous, the muscular fibre being distinguishable from that of the tendon only by its striation. But where the muscular fibre joins the tendon or aponeurosis at an oblique angle the former terminates, according to Kölliker, in rounded extremities, which are received into corresponding depressions on the surface of the latter, the connective tissue between the fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the Gastrocnemius and Soleus.

The fascia (fascia, a bandage) are fibro-aroeolar or aponeurotic laminae of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. The fasciae have been subdivided, from the situation in which they are found, into two groups, superficial and deep.

The superficial fascia is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep or aponeurotic
fascia, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. In the eyelids and scrotum, where adipose tissue is rarely deposited, this tissue is very liable to serous infiltration. The superficial fascia varies in thickness in different parts of the body: in the groin it is so thick as to be capable of being subdivided in several laminae, but in the palm of the hand it is of extreme thinness and intimately adherent to the integument. The superficial fascia is capable of separation into two or more layers, between which are found the superficial vessels and nerves, as the superficial epigastric vessels in the abdominal region, the radial and ulnar veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymphatic glands; certain cutaneous muscles also are situated in the superficial fascia, as the Platysma myoides in the neck, and the Orbicularis palpebrarum around the eyelids. This fascia is most distinct at the lower part of the abdomen, the scrotum, perineum, and extremities; is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the palms of the hands, and soles of the feet, forming a fibro-fatty layer which binds the integument firmly to the subjacent structure.

The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft medium for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areola is a bad conductor of heat.

The deep fascia is a dense, inelastic, unyielding fibrous membrane, forming sheaths for the muscles and affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It is usually exposed on the removal of the superficial fascia, forming a strong investment, which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciae are thick in unprotected situations, as on the outer side of a limb, and thinner on the inner side. The deep fasciae assist the muscles in their action by the degree of tension and pressure they make upon their surface; and in certain situations this is increased and regulated by muscular action; as, for instance, by the Tensor vaginæ femoris and Gluteus maximus in the thigh, by the Biceps in the upper and lower extremities, and Palmaris longus in the hand. In the limbs the fascia not only invest the entire limb, but give off septa which separate the various muscles, and are attached beneath to the periosteum: these prolongations of fasciae are usually spoken of as intermuscular septa.

The Muscles and Fasciae may be arranged, according to the general division of the body, into those of the cranium, face, and neck; those of the trunk; those of the upper extremity; and those of the lower extremity.

MUSCLES AND FASCIÆ OF THE CRANIUM AND FACE.

The muscles of the Cranium and Face consist of ten groups, arranged according to the region in which they are situated:

1. Cranial Region.
2. Auricular Region.
3. Palpebral Region.
4. Orbital Region.
5. Nasal Region.
6. Superior Maxillary Region.
7. Inferior Maxillary Region.
8. Intermaxillary Region.
9. Temporo-maxillary Region.
10. Pterygo-maxillary Region.

The muscles contained in each of these groups are the following:

1. Cranial Region.
   Occipito-frontalis.

2. Auricular Region.
   Atollens aurem.
   Attrahens aurem.
   Retrahens aurem.
3. Palpebral Region.
Orbicularis palpbrarum.
Corrugator supercilii.
Tensor tarsi.

4. Orbital Region.
Levator palpebrae.
Rectus superior.
Rectus inferior.
Rectus internus.
Rectus externus.
Obliquus superior.
Obliquus inferior.

5. Nasal Region.
Pyramidalis nasi.
Levator labii superioris alæque nasi.
Dilatatör naris posterior.
Dilatatör naris anterior.
Compressor nasii.
Compressor narium minor.
Depressor alæ nasi.

6. Superior Maxillary Region.
Levator labii superioris.
Levator anguli oris.
Zygomaticus major.
Zygomaticus minor.

7. Inferior Maxillary Region.
Levator labii inferioris.
Depressor labii inferioris.
Depressor anguli oris.

8. Intermaxillary Region.
Buccinator.
Risorius.
Orbicularis oris.

9. Temporo-maxillary Region.
Masseter.
Temporal.

10. Pterygo-maxillary Region.
Pterygoideus externus.
Pterygoideus internus.

1. Cranial Region—Occipito-frontalis.
Dissection (Fig. 268).—The head being shaved, and a block placed beneath the back of the neck, make a vertical incision through the skin from before backward, commencing at the root of the nose in front, and terminating behind at the occipital protuberance; make a second incision in a horizontal direction along the forehead and round the side of the head, from the anterior to the posterior extremity of the preceding. Raise the skin in front, from the subjacent muscle, from below upward; this must be done with extreme care, removing the integument from the outer surface of the vessels and the nerves which lie between the two.

The Skin of the Scalp.—This is thicker than in any other part of the body. It is intimately adherent to the superficial fascia. The hair-follicles are very closely
set together, and extend throughout the whole thickness of the skin. It also contains a number of sebaceous glands.

The **superficial fascia** in the cranial region is a firm, dense, fibro-fatty layer, intimately adherent to the integument, and to the Occipito-frontalis and its tendinous aponeurosis; it is continuous, behind, with the superficial fascia at the back part of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much granular fat.

The **Occipito-frontalis** (Fig. 269) is a broad musculo-fibrous layer, which covers the whole of one side of the vertex of the skull, from the occiput to the eyebrow. It consists of two muscular slips, separated by an intervening tendinous aponeurosis. The **occipital portion**, thin, quadrilateral in form, and about an inch and a half in length, arises from the outer two-thirds of the superior curved line of the occipital bone, and from the mastoid portion of the temporal. Its fibres of origin are tendinous, but they soon become muscular, and ascend in a parallel direction to

---

**Fig. 269.—Muscles of the head, face, and neck.**
terminate in a tendinous aponeurosis. The frontal portion is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader, its fibres are longer, and their structure paler than the occipital portion. Its internal fibres are continuous with those of the Pyramidalis nasi. Its middle fibres become blended with the Corrugator supercilii and Orbicularis palpebrarum; and the outer fibres are also blended with the latter muscle over the external angular process. According to Theile, the innermost fibres are attached to the nasal bones, the outer to the external angular process of the frontal bone. From these attachments the fibres are directed upward, and join the aponeurosis below the coronal suture. The inner margins of the frontal portions of the two muscles are joined together for some distance above the root of the nose; but between the occipital portions there is a considerable, though variable, interval, which is occupied by the aponeurosis.

The aponeurosis covers the upper part of the vertex of the skull, being continuous across the middle line with the aponeurosis of the opposite muscle. Behind, it is attached, in the interval between the occipital origins, to the occipital protuberance and superior curved lines above the attachment of the Trapezius; in front, it forms a short and narrow prolongation between the frontal portions; and on each side it has connected with it the Attollens and Attrahens aurem muscles; in this situation it loses its aponeurotic character, and is continued over the temporal fascia to the zygoma as a layer of laminated areolar tissue. This aponeurosis is closely connected to the integument by the firm, dense, fibro-fatty layer, which forms the superficial fascia; it is connected with the pericranium by loose cellular tissue, which allows of a considerable degree of movement of the integument.

Nerves.—The frontal portion of the Occipito-frontalis is supplied by the facial nerve; its occipital portion by the posterior auricular branch of the facial, and sometimes by the occipitalis minor.

Actions.—The frontal portion of the muscle raises the eyebrows and the skin over the root of the nose, and at the same time draws the scalp forward, throwing the integument of the forehead into transverse wrinkles. The posterior portion draws the scalp backward. By bringing alternately into action the frontal and occipital portions the entire scalp may be moved forward and backward. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the posterior portion, thus giving to the face the expression of surprise: if the action is more exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

2. Auricular Region (Fig. 269).

Attrahens aurem. Attollens aurem.

Retrahens aurem.

These three small muscles are placed immediately beneath the skin around the external ear. In man, in whom the external ear is almost immoveable, they are rudimentary. They are the analogues of large and important muscles in some of the mammalia.

Dissection.—This requires considerable care, and should be performed in the following manner: To expose the Attollens aurem, draw the pinna or broad part of the ear downward, when a tense band will be felt beneath the skin, passing from the side of the head to the upper part of the concha; by dividing the skin over this band, in a direction from below upward, and then reflecting it on each side, the muscle is exposed. To bring into view the Attrahens aurem, draw the helix backward by means of a hook, when the muscle will be made tense, and may be exposed in a similar manner to the preceding. To expose the Retrahens aurem, draw the pinna forward, when the muscle, being made tense, may be felt beneath the skin at its insertion into the back part of the concha, and may be exposed in the same manner as the other muscles.

The Attrahens aurem (Auricularis anterior), the smallest of the three, is thin, fan-shaped, and its fibres pale and indistinct; they arise from the lateral edge of
the aponeurosis of the Occipito-frontalis, and converge to be inserted into a projection on the front of the helix.

Relations.—Superficially, with the skin; deeply, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which are the temporal artery and vein and the temporal fascia.

The Attollens aurem (Auricularis superior), the largest of the three, is thin and fan-shaped: its fibres arise from the aponeurosis of the Occipito-frontalis and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the pinna.

Relations.—Superficially, with the integument; deeply, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which is the temporal fascia.

The Retrahens aurem (Auricularis posterior) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotive fibres. They are inserted into the lower part of the cranial surface of the concha.

Relations.—Superficially, with the integument; deeply, with the mastoid portion of the temporal bone.

Nerves.—The Attrahens and Attollens aurem are supplied by the temporal branch of the facial; the Retrahens aurem is supplied by the posterior auricular branch of the same nerve.

Actions.—In man, these muscles possess very little action: the Attrahens aurem draws the ear forward and upward; the Attollens aurem slightly raises it; and the Retrahens aurem draws it backward.

3. Palpebral Region (Fig. 269).

Ocularis palpebrarum. Levator palpebre.
Corrugator supercili. Tensor tarsi.

Dissection (Fig. 256).—In order to expose the muscles of the face, continue the longitudinal incision made in the dissection of the Occipito-frontalis down the median line of the face to the tip of the nose, and from this point onward to the upper lip; and carry another incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the jaw. Then make an incision in front of the external ear, from the angle of the jaw upward, to join the transverse incision made in exposing the Occipito-frontalis. These incisions include a square-shaped flap, which should be removed in the direction marked in the figure, with care, as the muscles at some points are intimately adherent to the integument.

The Orbicularis palpebrarum is a sphincter muscle, which surrounds the circumference of the orbit and eyelids. It arises from the internal angular process of the frontal bone, from the nasal process of the superior maxillary in front of the lachrymal groove for the nasal duct, and from the anterior surface and borders of a short tendon, the tendo palpebrarum, placed at the inner angle of the orbit. From this origin the fibres are directed outward, forming a broad, thin, and flat layer, which covers the eyelids, surrounds the circumference of the orbit, and spreads out over the temple and downward on the cheek. The palpebral portion (ciliaris) of the Orbicularis is thin and pale; it arises from the bifurcation of the tendo palpebrarum, and forms a series of concentric curves, which are united on the outer side of the eyelids at an acute angle by a cellular raphe, some being inserted into the external tarsal ligament and malar bone. The orbicular portion (orbicularis latus) is thicker and of a reddish color; its fibres are well developed, and form complete ellipses. The upper fibres of this portion blend with the Occipito-frontalis and Corrugator supercili.

Relations.—By its superficial surface, with the integument. By its deep surface, above, with the Occipito-frontalis and Corrugator supercili, with which it is intimately blended, and with the supra-orbital vessels and nerve; below, it covers the lachrymal sac, and the origin of the Levator labii superioris alaeque nasi, the Levator labii superioris, and the Zygomaticus minor muscles. Inter-
nally, it is occasionally blended with the Pyramidalis nasi. Externally, it lies on the temporal fascia. On the eyelids it is separated from the conjunctiva by the Levator palpebræ, the tarsal ligaments, the tarsal plates, and the Meibomian glands.

The *tendo palpebrarum* (tendo oculi) is a short tendon, about two lines in length and one in breadth, attached to the nasal process of the superior maxillary bone in front of the lacrimal groove for the nasal duct. Crossing the lacrimal sac, it divides into two parts, each division being attached to the inner extremity of the corresponding tarsal plate. As the tendon crosses the lacrimal sac, a strong aponeurotic lamina is given off from the posterior surface, which expands over the sac, and is attached to the ridge on the lacrimal bone. This is the reflected aponeurosis of the *tendo palpebrarum*.

**Use of Tendo oculi.**—Besides giving attachment to part of the Orbicularis palpebrarum, and to the tarsal plates, it serves to suck the tears into the lacrimal sac, by its attachment to the sac. Thus, each time the eyelids are closed, the *tendo oculi* becomes tightened, and draws the wall of the lacrimal sac outward and forward, so that a vacuum is made in the sac, and the tears are sucked along the lacrimal canals into it.

The *Corrugator supercilii* is a small, narrow, pyramidal muscle, placed at the inner extremity of the eyebrow, beneath the Occipito-frontalis and Orbicularis palpebrarum muscles. It arises from the inner extremity of the superciliary ridge; from whence its fibres pass upward and outward, to be inserted into the under surface of the orbicularis, opposite the middle of the orbital arch.

**Relations.**—By its anterior surface with the Occipito-frontalis and Orbicularis palpebrarum muscles; by its posterior surface, with the frontal bone and supratrochlear nerve.

The *Levator palpebræ* will be described with the muscles of the orbital region.

The *Tensor tarsi* (Horner's muscle) (Fig. 270) is a small thin muscle about three lines in breadth and six in length, situated at the inner side of the orbit, behind the tendo oculi. It arises from the crest and adjacent part of the orbital surface of the lacrimal bone, and, passing across the lacrimal sac, divides into two slips, which cover the lacrimal canals, and are inserted into the tarsal plates internal to the puncta lachrymalia. Its fibres appear to be continuous with those of the palpebral portion of the Orbicularis palpebrarum; it is occasionally very indistinct.

**Nerves.**—The Orbicularis palpebrarum, Corrugator supercilii, and Tensor tarsi are supplied by the facial nerve.

**Actions.**—The Orbicularis palpebrarum is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbicular portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn inward toward the inner angle of the orbit, and the eyelids are firmly closed as in photophobia. When the skin of the forehead, temple, and cheek is thus drawn inward by the
action of the muscle it is thrown into folds, especially radiating from the outer angle of the eyelids, which give rise in old age to the so-called "crow's feet." The Levator palpebræ is the direct antagonist of this muscle; it raises the upper eyelid and exposes the globe. The Corrugator superciliī draws the eyebrow downward and inward, producing the vertical wrinkles of the forehead. It is the "frowning" muscle, and may be regarded as the principal agent in the expression of suffering. The Tensor tarsi draws the eyelids and the extremities of the lachrymal canals inward and compresses them against the surface of the globe of the eye; thus placing them in the most favorable situation for receiving the tears. It serves, also, to compress the lachrymal sac.

4. Orbital Region (Fig. 271).

Dissection.—To open the cavity of the orbit, remove the skull-cap and brain; then saw through the frontal bone at the inner extremity of the supraorbital ridge, and externally at its junction with the malar. Break in pieces the thin roof of the orbit by a few slight blows of the hammer, and take it away; drive forward the superciliary portion of the frontal bone by a smart stroke, but do not remove it, as that would destroy the pulley of the Obliquus superior. When the fragments are cleared away, the periosteum of the orbit will be exposed; this being removed, together with the fat which fills the cavity of the orbit, the several muscles of this region can be examined. The dissection will be facilitated by distending the globe of the eye. In order to effect this, puncture the optic nerve near the eyeball with a curved needle, and push the needle onward into the globe; insert the point of a blowpipe through this aperture, and force a little air into the cavity of the eyeball; then apply a ligature round the nerve so as to prevent the air escaping. The globe being now drawn forward, the muscles will be put upon the stretch.

The Levator palpebræ superioris is thin, flat, and triangular in shape. It arises from the under surface of the lesser wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the Superior rectus, and is inserted, by a broad aponeurosis, into the anterior surface of the superior tarsal plate. From this aponeurosis a thin expansion is continued onward, passing between the fibres of the Orbicularis to be inserted into the skin of the lid. At its origin it is narrow and tendinous, but soon becomes broad and fleshy, and finally terminates in a broad aponeurosis.

Relations.—By its upper surface, with the frontal nerve and supraorbital
artery, the periosteum of the orbit, and, in the lid, with the inner surface of the tarsal ligament; by its under surface, with the Superior rectus, and, in the lid, with the conjunctiva. A small branch of the third nerve enters its under surface.

The Superior rectus, the thinnest and narrowest of the four Recti, arises from the upper margin of the optic foramen beneath the Levator palpebrae and Superior oblique, and from the fibrous sheath of the optic nerve, and is inserted by a tendinous expansion into the sclerotic coat, about three or four lines from the margin of the cornea.

Relations.—By its upper surface, with the Levator palpebrae; by its under surface, with the optic nerve, the ophthalmic artery, the nasal nerve, and the branch of the third nerve which supplies it; and, in front, with the tendon of the Superior oblique and the globe of the eye.

The Inferior and Internal Recti arise by a common tendon (the ligament of Zinn), which is attached round the circumference of the optic foramen, except at its upper and outer part. The External rectus has two heads: the upper one arises from the outer margin of the optic foramen immediately beneath the Superior rectus; the lower head, partly from the ligament of Zinn and partly from a small pointed process of bone on the lower margin of the sphenoidal fissure. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion (the tunica albuginea) into the sclerotic coat, about three or four lines from the margin of the cornea. Between the two heads of the External rectus is a narrow interval, through which passes the third, the nasal branch of the ophthalmic division of the fifth and sixth nerves, and the ophthalmic vein. Although nearly all of these muscles present a common origin and are inserted in a similar manner into the sclerotic coat, there are certain differences to be observed in them as regards their length and breadth. The Internal rectus is the broadest, the External is the longest, and the Superior is the thinnest and narrowest.

The Superior oblique is a fusiform muscle placed at the upper and inner side of the orbit, internal to the Levator palpebrae. It arises about a line above the inner margin of the optic foramen, and, passing forward to the inner angle of the orbit, terminates in a rounded tendon, which plays in a ring or pulley (trochlea) formed by fibro-cartilaginous tissue attached to a depression beneath the internal angular process of the frontal bone, the contiguous surfaces of the tendon and ring being lined by a delicate synovial membrane and enclosed in a thin fibrous investment. The tendon is reflected backward, outward, and downward beneath the Superior rectus to the outer part of the globe of the eye, and is inserted into the sclerotic coat, midway between the cornea and entrance of the optic nerve, the insertion of the muscle lying between the Superior and External recti.

Relations.—By its upper surface, with the periosteum covering the roof of the orbit and the fourth nerve: the tendon, where it lies on the globe of the eye is covered by the Superior rectus; by its under surface, with the nasal nerve and the upper border of the internal rectus.

The Inferior oblique is a thin, narrow muscle placed near the anterior margin of the orbit. It arises from a depression on the orbital plate of the superior

---

1 The ligament of Zinn ought, perhaps more appropriately, to be termed the aponeurosis or tendon of Zinn. Mr. C. B. Lockwood has described a somewhat similar structure on the under surface of the Superior rectus muscle, which is attached to the lesser wing of the sphenoid, forming the upper and outer margin of the optic foramen. This superior tendon gives origin to the Superior rectus, the superior head of the External rectus, and the upper part of the Internal rectus. (Journal of Anatomy and Physiology, vol. xx. part i. p. 1.)
maxillary bone, external to the lachrymal groove for the nasal duct. Passing outward, backward, and upward beneath the Inferior rectus, and then between the eyeball and the External rectus, it is inserted into the outer part of the sclerotic coat between the Superior and External recti, near to, but somewhat behind, the tendon of insertion of the Superior oblique.

**Relations.**—By its ocular surface, with the globe of the eye and with the Inferior rectus; by its orbital surface, with the periosteum covering the floor of the orbit, and with the External rectus. Its borders look forward and backward; the posterior one receives a branch of the third nerve.

**Nerves.**—The Levator palpebræ, Inferior oblique, and all the Recti excepting the External, are supplied by the third nerve; the Superior oblique, by the fourth; the External rectus, by the sixth.

**Actions.**—The Levator palpebræ raises the upper eyelid, and is the direct antagonist of the Orbicularis palpebrarum. The four Recti muscles are attached in such a manner to the globe of the eye that, acting singly, they will turn it either upward, downward, inward, or outward, as expressed by their names. The movement produced by the Superior or Inferior rectus is not quite a simple one, for, inasmuch as they pass obliquely outward and forward to the eyeball, the elevation or depression of the cornea must be accompanied by a certain deviation inward, with a slight amount of rotation, which, however, is corrected by the Oblique muscles, the Inferior oblique correcting the deviation inward of the Superior rectus, and the Superior oblique that of the Inferior rectus. The contraction of the External and Internal recti, on the other hand, produces a purely horizontal movement. If any two contiguous recti of one eye act together, they carry the globe of the eye in the diagonal of these directions—viz. upward and inward, upward and outward, downward and inward, or downward and outward. The movement of circumduction, as in looking round a room, is performed by the alternate action of the four Recti. The Oblique muscles rotate the eyeball on its antero-posterior axis, this kind of movement being required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of each eye.\(^1\)

**Surgical Anatomy.**—The position and exact point of insertion of the tendons of the Internal and External recti muscles into the globe should be carefully examined from the front of the eyeball, as the surgeon is often required to divide the one or the other muscle for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned inward, requiring the division of the Internal rectus. In the divergent form, which is more rare, the eye is turned outward, the External rectus being especially implicated. The deformity produced in either case is to be remedied by division of one or the other muscle. The operation is thus performed: The lids are to be well separated; the eyeball being rotated outward or inward, the conjunctiva should be raised by a pair of forceps and divided immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclerotic; the submucous areolar tissue is then divided, and into the small aperture thus made a blunt hook is passed upward between the muscle and the globe, and the tendon of the muscle and conjunctiva covering it divided by a pair of blunt-pointed scissors. Or the tendon may be divided by a subconjunctival incision, one blade of the scissors being passed upward between the tendon and the conjunctiva, and the other between the tendon and the sclerotic. The student, when dissecting these muscles, should remove on one side of the subject the conjunctiva from the front of the eye, in order to see more accurately the position of the tendons, while on the opposite side the operation may be performed.

5. Nasal Region (Fig. 269).

- Pyramidalis nasi.
- Levator labii superioris alaeque nasi.
- Dilatator naris posterior.
- Dilatator naris anterior.
- Compressor nasi.
- Compressor narium minor.
- Depressor alae nasi.

\(^1\) \textit{On the Oblique Muscles of the Eye in Man and Vertebrate Animals,"} by John Struthers, M. D., in \textit{Anatomical and Physiological Observations}. For a fuller account of the various co-ordinate actions of the muscles of a single eye and of both eyes than our space allows, the reader may be referred to Dr. M. Foster's \textit{Text-book of Physiology}. 
The **Pyramidalis nasi** is a small pyramidal slip prolonged downward from the Occipito-frontalis upon the side of the nose, where it becomes tendinous and blends with the Compressor nasi. As the two muscles descend they diverge, leaving an angular interval between them.

**Relations.**—By its *upper surface*, with the skin; by its *under surface*, with the frontal and nasal bones.

The **Levator labii superioris alaeque nasi** is a thin triangular muscle placed by the side of the nose, and extending between the inner margin of the orbit and upper lip. It arises by a pointed extremity from the upper part of the nasal process of the superior maxillary bone, and, passing obliquely downward and outward, divides into two slips, one of which is inserted into the cartilage of the ala of the nose; the other is prolonged into the upper lip, becoming blended with the Orbicularis oris and Levator labii superioris proprius.

**Relations.**—In front, with the integument, and with a small part of the Orbicularis palpebrarum above.

The **Dilatator naris posterior** is a small muscle which is placed partly beneath the elevator of the nose and lip. It arises from the margin of the nasal notch of the superior maxilla and from the sesamoid cartilages, and is inserted into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a thin delicate fasciculus passing from the cartilage of the ala of the nose to the integument near its margin. This muscle is situated in front of the preceding.

The **Compressor nasi** is a small, thin, triangular muscle arising by its apex from the superior maxillary bone, above and a little external to the incisive fossa; its fibres proceed upward and inward, expanding into a thin aponeurosis which is attached to the fibro-cartilage of the nose and is continuous on the bridge of the nose with that of the muscle of the opposite side and with the aponeurosis of the Pyramidalis nasi.

The **Compressor narium minor** is a small muscle attached by one end to the alar cartilage, and by the other to the integument at the end of the nose.

The **Depressor alae nasi** is a short radiated muscle arising from the incisive fossa of the superior maxilla; its fibres ascend to be inserted into the septum and back part of the ala of the nose. This muscle lies between the mucous membrane and muscular structure of the lip.

**Nerves.**—All the muscles of this group are supplied by the facial nerve.

**Actions.**—The Pyramidalis nasi draws down the inner angle of the eyebrows and produces transverse wrinkles over the bridge of the nose; by some anatomists it is also considered as an elevator of the ala, and, consequently, a dilator of the nose. The Levator labii superioris alaeque nasi draws upward the upper lip and ala of the nose: its most important action is upon the nose, which it dilates to a considerable extent. The action of this muscle produces a marked influence over the countenance, and it is the principal agent in the expression of contempt and disdain. The two Dilatatores nasi enlarge the aperture of the nose. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing they may be noticed to be in violent action, as well as in some emotions, as anger. The Depressor alae nasi is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downward, and thereby constricting the aperture of the nares. The Compressor nasi depresses the cartilaginous part of the nose and compresses the alæ together.

1 Although this muscle anatomically seems to be a continuation of the Occipito-frontalis downward, it is really the reverse. Its origin is from the nose below, and its insertion into the Occipito-frontalis and skin. If one pole of a battery be placed in front of the lobe of the ear, and the other (a small pointed one) be carried up and down over the nose and forehead in the middle line, it is easy to find a nodal point of indifference above which the Occipito-frontalis draws the parsis upward, and below which the Pyramidalis draws them downward (W. W. Keen, M. D., American edition).
6. Superior Maxillary Region (Fig. 269).

By  
\[ \text{Levator labii superioris.} \]  
\[ \text{Zygomaticus major.} \]
\[ \text{Levator anguli oris.} \]  
\[ \text{Zygomaticus minor.} \]

The Levator labii superioris (proprius) is a thin muscle of a quadrilateral form. It arises from the lower margin of the orbit immediately above the infraorbital foramen, some of its fibres being attached to the superior maxilla, others to the malar bone; its fibres converge to be inserted into the muscular substance of the upper lip.

Relations.—By its superficial surface above, with the lower segment of the Orbicularis palpebrarum; below, it is subcutaneous. By its deep surface it conceals the origin of the Compressor nasi and Levator anguli oris muscles, and the infraorbital vessels and nerve, as they escape from the infraorbital foramen.

The Levator anguli oris arises from the canine fossa immediately below the infraorbital foramen; its fibres incline downward and a little outward, to be inserted into the angle of the mouth, intermingling with those of the Zygomaticus major, the Depressor anguli oris, and the Orbicularis.

Relations.—By its superficial surface, with the Levator labii superioris and the infraorbital vessels and nerves; by its deep surface, with the superior maxilla, the Buccinator, and the mucus membrane.

The Zygomaticus major is a slender fasciculus which arises from the malar bone, in front of the zygomatic suture, and, descending obliquely downward and inward, is inserted into the angle of the mouth, where it blends with the fibres of the Levator anguli oris, the Orbicularis oris, and the Depressor anguli oris.

Relations.—By its superficial surface, with the subcutaneous adipose tissue; by its deep surface, with the malar bone and the Masseter and Buccinator muscles.

The Zygomaticus minor arises from the malar bone immediately behind the maxillary suture, and, passing downward and inward, is continuous with the Orbicularis oris at the outer margin of the Levator labii superioris. It lies in front of the preceding.

Relations.—By its superficial surface, with the integument and the Orbicularis palpebrarum above; by its deep surface, with the Masseter, Buccinator, and Levator anguli oris.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii superioris is the proper elevator of the upper lip, carrying it at the same time a little forward. It assists in forming the naso-labial ridge, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. The Levator anguli oris raises the angle of the mouth, and assists the Levator labii superioris in producing the naso-labial ridge. The Zygomaticus major draws the angle of the mouth backward and upward, as in laughing; whilst the Zygomaticus minor, being inserted into the outer part of the upper lip and not into the angle of the mouth, draws it backward, upward, and outward, and thus gives to the face an expression of sadness.

7. Inferior Maxillary Region (Fig. 269).

\[ \text{Levator labii inferioris (Levator menti).} \]
\[ \text{Depressor labii inferioris (Quadratus menti).} \]
\[ \text{Depressor anguli oris (Triangularis menti).} \]

Dissection.—The muscles in this region may be dissected by making a vertical incision through the integument from the margin of the lower lip to the chin: a second incision should then be carried along the margin of the lower jaw as far as the angle, and the integument carefully removed in the direction shown in Fig. 268.

The Levator labii inferioris (Levator menti) is to be dissected by everting the lower lip and raising the mucous membrane. It is a small conical fasciculus placed on the side of the frenum of the lower lip. It arises from the incisive fossa,
external to the symphysis of the lower jaw; its fibres descend to be inserted into the integument of the chin.

Relation.—On its inner surface, with the mucous membrane; in the median line, it is blended with the muscle of the opposite side; and on its outer side, with the Depressor labii inferioris.

The Depressor labii inferioris (Quadratus menti) is a small quadrilateral muscle. It arises from the external oblique line of the lower jaw, between the symphysis and mental foramen, and passes obliquely upward and inward, to be inserted into the integument of the lower lip, its fibres blending with the Orbicularis oris and with those of its fellow of the opposite side. It is continuous with the fibres of the Platysma at its origin. This muscle contains much yellow fat intermingled with its fibres.

Relations.—By its superficial surface, with part of the Depressor anguli oris and with the integument, to which it is closely connected; by its deep surface, with the mental vessels and nerves, the mucous membrane of the lower lip, the labial glands, and the Levator menti, with which it is intimately united.

The Depressor anguli oris (Triangularis menti) is triangular in shape, arising, by its broad base, from the external oblique line of the lower jaw, from whence its fibres pass upward, to be inserted, by a narrow fasciculus, into the angle of the mouth. It is continuous with the Platysma at its origin and with the Orbicularis oris and Risorius at its insertion, and some of its fibres are directly continuous with those of the Levator anguli oris.

Relations.—By its superficial surface, with the integument; by its deep surface, with the Depressor labii inferioris and Buccinator.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii inferioris raises the lower lip and protrudes it forward, and at the same time wrinkles the integument of the chin, expressing doubt or disdain. The Depressor labii inferioris draws the lower lip directly downward and a little outward, as in the expression of irony. The Depressor anguli oris depresses the angle of the mouth, being the antagonist to the Levator anguli oris and Zygomaticus major; acting with these muscles, it will draw the angle of the mouth directly backward.

8. Intermaxillary Region.

Dissection.—The dissection of these muscles may be considerably facilitated by filling the cavity of the mouth with tow, so as to distend the cheeks and lips; the mouth should then be closed by a few stitches and the integument carefully removed from the surface.

The Orbicularis oris (Fig. 269) is not a spherimeter muscle, like the Orbicularis palpebrarum, but consists of numerous strata of muscular fibres, having different directions, which surround the orifice of the mouth. These fibres are partially derived from the other facial muscles which are inserted into the lips, and are partly fibres proper to the lips themselves. Of the former, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of them—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the upper jaw passing to the lower lip, and those from the lower jaw to the upper lip. Other fibres of the muscle, situated at its upper and lower part, pass across the lips from side to side without interruption. Superficial to this stratum is a second, formed by the Levator and Depressor anguli oris, which cross each other at the angle of the mouth, those from the Depressor passing to the upper lip, and those from the Levator to the lower lip, along which they run to be inserted into the skin near the median line. In addition to these there are fibres from the other muscles inserted into the lips—the Levator labii superioris, the Levator labii superioris alaeque nasi, the Zygomatici, and the Depressor labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of
the lips are oblique, and pass from the under surface of the skin to the mucous membrane through the thickness of the lip. And in addition to these are fibres by which the muscle is connected directly with the maxillary bones and the septum of the nose. These consist, in the upper lip, of four bands, two of which (Accessory orbicularis superioris) arise from the alveolar border of the superior maxilla, opposite the lateral incisor tooth, and, arching outward on each side, are continuous at the angles of the mouth with the other muscles inserted into this part. The two remaining muscular slips, called the Naso-labialis, connect the upper lip to the back of the septum of the nose: as they descend from the septum an interval is left between them. It is this interval which forms the depression (philtrum) seen on the surface of the skin beneath the septum of the nose. The additional fibres for the lower segment (Accessory orbicularis inferioris) arise from the inferior maxilla, externally to the Levator labii inferioris, and arch outward to the angles of the mouth, to join the Buccinator and the other muscles attached to this part.

Relations.—By its superficial surface, with the integument, to which it is closely connected; by its deep surface, with the buccal mucous membrane, the labial glands, and coronary vessels; by its outer circumference it is blended with the numerous muscles which converge to the mouth from various parts of the face. Its inner circumference is free, and covered by the mucous membrane.

The Buccinator (Fig. 282) is a broad, thin muscle, quadrilateral in form, which occupies the interval between the jaws at the side of the face. It arises from the outer surface of the alveolar processes of the upper and lower jaws, corresponding to the three molar teeth, and, behind, from the anterior border of the pterygo-maxillary ligament. The fibres converge toward the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the inferior segment; the highest and lowest fibres continue forward uninterrupted into the corresponding segment of the lip, without decussation.

Relations.—By its superficial surface, behind, with a large mass of fat, which separates it from the ramus of the lower jaw, the Masseter, and a small portion of the Temporal muscle; anteriorly, with the Zygomatici, Risorius, Levator anguli oris, Depressor anguli oris, and Stenson’s duct, which pierces it opposite the second molar tooth of the upper jaw; the facial artery and vein cross it from below upward; it is also crossed by the branches of the facial and buccal nerves; by its internal surface, with the buccal glands and mucous membrane of the mouth.

The pterygo-maxillary ligament separates the Buccinator muscle from the Superior constrictor of the pharynx. It is a tendinous band, attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the internal oblique line of the lower jaw. Its inner surface corresponds to the cavity of the mouth, and is lined by mucous membrane. Its outer surface is separated from the ramus of the jaw by a quantity of adipose tissue. Its posterior border gives attachment to the Superior constrictor of the pharynx; its anterior border, to the fibres of the Buccinator (see Fig. 282).

The Risorius (Santorini) (Fig. 269) consists of a narrow bundle of fibres which arises in the fascia over the Masseter muscle, and, passing horizontally forward, is inserted into the skin at the angle of the mouth. It is placed superficial to the Platysma, and is broadest at its posterior extremity. This muscle varies much in its size and form.

Nerves.—The Orbicularis oris and the Risorius are supplied by the facial, the Buccinator by the facial and by the buccal branch of the inferior maxillary nerve; which latter, however, is by many anatomists regarded as a sensory nerve only.

Actions.—The Orbicularis oris in its ordinary action produces the direct closure of the lips; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forward. The Buccinators contract and compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When
the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet. Hence the name (buccina, a trumpet). The Risorius retracts the angles of the mouth, and is therefore regarded as the "smiling" muscle.

9. Temporo-maxillary Region.

\[ \text{Masseteric Fascia.} \]

Covering the Masseter muscle, and firmly connected with it, is a strong layer of fascia derived from the deep cervical fascia. Above, this fascia is attached to the lower border of the zygoma, and, behind, it covers the parotid gland, constituting the parotid fascia.

The Masseter is exposed by the removal of this fascia (Fig. 269); it is a short, thick muscle, somewhat quadrilateral in form, consisting of two portions, superficial and deep. The superficial portion, the larger, arises by a thick, tendinous aponeurosis from the malar process of the superior maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch; its fibres pass downward and backward, to be inserted into the angle and lower half of the outer surface of the ramus of the jaw. The deep portion is much smaller and more muscular in texture; it arises from the posterior third of the lower border and the whole of the inner surface of the zygomatic arch; its fibres pass downward and forward, to be inserted into the upper half of the ramus and outer surface of the coronoid process of the jaw. The deep portion of the muscle is partly concealed, in front by the superficial portion; behind, it is covered by the parotid gland. The fibres of the two portions are united at their insertion.

\[ \text{Relations.} \]

By its superficial surface, with the Zygomatici, the Socia parotidis, and Stenson's duct; the branches of the facial nerve and the transverse facial vessels, which cross it; the masseteric fascia; the Risorius, Sanniorini, Platysma myoides, and the integument; by its deep surface, with the Temporal muscle at its insertion, the ramus of the jaw, and the Buccinator, from which it is separated by a mass of fat. The masseteric nerve and artery enter it on its deep surface. Its posterior margin is overlapped by the parotid gland. Its anterior margin projects over the Buccinator muscle, and the facial vein lies on it below.

The temporal fascia is seen, at this stage of the dissection covering in the Temporal muscle. It is a strong, fibrous investment, covered, on its outer surface, by the Attrahens and Attollens aurem muscles, the aponeurosis of the Occipitofrontalis, and by part of the Orbicularis palpebrarum. The temporal vessels and the auriculo-temporal nerve cross it from below upward. Above, it is a single layer, attached to the entire extent of the upper temporal ridge; but below, where it is attached to the zygoma, it consists of two layers, one of which is inserted into the outer, and the other into the inner, border of the zygomatic arch. A small quantity of fat, the orbital branch of the temporal artery, and a filament from the orbital, or temporo-malar, branch of the superior maxillary nerve, are contained between these two layers. It affords attachment by its inner surface to the superficial fibres of the Temporal muscle.

\[ \text{Dissection.} \]

In order to expose the Temporal muscle, remove the temporal fascia, which may be effected by separating it at its attachment along the upper border of the zygoma, and dissecting it upward from the surface of the muscle. The zygomatic arch should then be divided in front at its junction with the malar bone, and behind near the external auditory meatus, and drawn downward with the Masseter, which should be detached from its insertion into the ramus and angle of the jaw. The whole extent of the Temporal muscle is then exposed.

The Temporal (Fig. 273) is a broad, radiating muscle situated at the side of the head and occupying the entire extent of the temporal fossa. It arises from the whole of the temporal fossa except that portion of it that is formed by the malar bone. Its attachment extends from the external angular process of the frontal in front to the mastoid portion of the temporal behind, and from the curved line on the frontal and parietal bones above to the pterygoid ridge on the great wing of
the sphenoid below. It is also attached to the inner surface of the temporal fascia. Its fibres converge as they descend, and terminate in an aponeurosis, the fibres of which, radiated at its commencement, converge into a thick and flat tendon, which is inserted into the inner surface, apex, and anterior border of the coronoid process of the jaw, nearly as far forward as the last molar tooth.

Relations.—By its superficial surface, with the integument, the Attrahens and Attollens aremus muscles, the temporal vessels and nerves, the aponeurosis of the Occipito-frontalis, the temporal fascia, the zygoma, and Masseter; by its deep surface, with the temporal fossa, the External pterygoid and part of the Buccinator muscles, the internal maxillary artery, its deep temporal branches, and the deep temporal nerves. Behind the tendon are the masseteric vessels and nerve, and in front of it the buccal vessels and nerve. Its anterior border is separated from the malar bone by a mass of fat.

Nerves.—Both muscles are supplied by the inferior maxillary nerve.

10. Pterygo-maxillary Region (Fig. 274).

Dissection.—The Temporal muscle having been examined, saw through the base of the coronoid process, and draw it upward, together with the Temporal muscle, which should be detached from the surface of the temporal fossa. Divide the ramus of the jaw just below the condyle, and also, by a transverse incision extending across the middle, just above the dental foramen; remove the fragment, and the Pterygoid muscles will be exposed.

The External Pterygoid is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the zygomatic fossa and the condyle of the jaw. It arises from the pterygoid ridge on the great wing of the sphenoid and the portion of bone included between it and the base of the pterygoid process, and from the outer surface of the external pterygoid plate. Its fibres pass horizontally backward and outward, to be inserted into a depression in front of the neck of the condyle of the lower jaw and into the corresponding part of the interarticular fibro-cartilage. This muscle, at its origin, appears to consist of two portions separated by a slight interval; hence the terms upper and lower head sometimes used in the description of the muscle.

Relations.—By its external surface, with the ramus of the lower jaw, the
internal maxillary artery, which crosses it, the tendon of the Temporal muscle, and the Masseter; by its internal surface it rests against the upper part of the Internal pterygoid, the internal lateral ligament, the middle meningeal artery, and inferior maxillary nerve; by its upper border it is in relation with the temporal and masseteric branches of the inferior maxillary nerve; by its lower border it is in relation with the inferior dental and gustatory nerves, and it is pierced by the buccal nerve. In the interval between the two portions of the muscle the internal maxillary artery passes, when this vessel lies on the muscle (see Fig. 274).

The Internal Pterygoid is a thick, quadrilateral muscle, and resembles the Masseter in form. It arises from the pterygoid fossa, being attached to the inner surface of the external pterygoid plate and to the grooved surface of the tuberosity of the palate bone, and by a second slip from the outer surface of the tuberosity of the palate bone and from the tuberosity of the superior maxillary bone; its fibres pass downward, outward, and backward, to be inserted, by a strong, tendinous lamina, into the lower and back part of the inner side of the ramus and angle of the lower jaw, as high as the dental foramen.

Relations.—By its external surface, with the ramus of the lower jaw, from which it is separated, at its upper part, by the External pterygoid, the internal lateral ligament, the internal maxillary artery, the dental vessels and nerves, and the lingual nerve; by its internal surface, with the Tensor palati, being separated from the Superior constrictor of the pharynx by a cellular interval.

Nerves.—These muscles are supplied by the inferior maxillary nerve.

Actions.—The Temporal and Masseter and Internal pterygoid raise the lower jaw against the upper with great force. The superficial portion of the Masseter assists the External pterygoid in drawing the lower jaw forward upon the upper, the jaw being drawn back again by the deep fibres of the Masseter and posterior fibres of the Temporal. The External pterygoid muscles are the direct agents in the trituration of the food, drawing the lower jaw directly forward, so as to make the lower teeth project beyond the upper. If the muscle of one side acts, the corresponding side of the jaw is drawn forward, and, the other condyle remaining fixed, the symphysis deviates to the opposite side. The alternation of these movements on the two sides produces trituration.

1 This is the usual relation, but in many cases the artery will be found below the muscle
Surface Form.—The outline of the muscles of the head and face cannot be traced on the surface of the body, except in the case of two of the mastiatory muscles. Those of the head are thin, so that the outline of the bone is perceptible beneath them. Those in the face are small, covered by soft skin, and often by a considerable layer of fat, so that their outline is concealed, but they serve to round off and smooth prominent borders and to fill up what would be otherwise unsightly angular depressions. Thus, the Orbicularis palpebrarum rounds off the prominent margin of the orbit, and the Pyramidalis nasi fills in the sharp depression beneath the glabella, and thus softens and tones down the abrupt depression which is seen on the unclothed bone. In like manner, the labial muscles, converging to the lips and assisted by the superimposed fat, fill in the sunken hollow of the lower part of the face. Although the muscles of the face are usually described as arising from the bones and inserted into the nose, lips, and corners of the mouth, they have fibres inserted into the skin of the face along their whole extent, so that almost every point of the skin of the face has its muscular fibre to move it; hence it is that when in action the facial muscles produce alterations in the skin-surface, giving rise to the formation of various folds or wrinkles, or otherwise altering the relative position of parts, so as to produce the varied expressions with which the face is endowed; hence these muscles are termed the "muscles of expression." The only two muscles in this region which greatly influence surface form are the Masseter and the Temporal. The Masseter is a quadrilateral muscle, which imparts fullness to the hinder part of the cheek. When the muscle is firmly contracted, as when the teeth are clenched, its outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fulness, especially marked at the lower part of the muscle; this fulness is entirely lost when the mouth is opened and the muscle no longer in a state of contraction. The Temporal muscle is fan-shaped, and fills the Temporal fossa, substituting for it a somewhat convex form, the anterior part of which, on account of the absence of hair over the temple, is more marked than the posterior, and stands out in strong relief when the muscle is in a state of contraction.

Muscles and Fasciae of the Neck.

The muscles of the neck may be arranged into groups corresponding with the region in which they are situated.

These groups are nine in number:
1. Superficial cervical region.
2. Depressors of the Os Hyoides and Larynx.
3. Elevators of the Os Hyoides and Larynx.
4. Muscles of the Tongue.
5. Muscles of the Pharynx.
7. Muscles of the Anterior Ver-tebral Region.
8. Muscles of the Lateral Ver-tebral Region.

The muscles contained in each of these groups are the following:

1. Superficial Region.
   - Platysma myoides.
   - Sterno-cleido-mastoid.

   Infra-hyoid Region.

2. Depressors of the Os hyoides and Larynx.
   - Sterno-hyoid.
   - Sterno-thyroid.
   - Thyro-hyoid.
   - Omo-hyoid.

   Supra-hyoid Region.

3. Elevators of the Os hyoides and Larynx.
   - Digastric.
   - Stylo-hyoid.
   - Mylo-hyoid.
   - Genio-hyoid.

   Lingual Region.

4. Muscles of the Tongue.
   - Genio-hyo-glossus.
   - Hyo-glossus.
   - Lingualis.
   - Stylo-glossus.
   - Palato-glossus.

   Constrictor inferior.
   - Constrictor medius.
   - Constrictor superior.
   - Stylo-pharyngeus.
   - Palato-pharyngeus.

   - Levator palati.
   - Tensor palati.
   - Azygos uvulae.
   - Palato-glossus.
   - Palato-pharyngeus.
7. **Muscles of the Anterior Vertebral Region.**
- Rectus capitis anticus major.
- Rectus capitis anticus minor.
- Rectus lateralis.
- Longus colli.

8. **Muscles of the Lateral Vertebral Region.**
- Scalenus anticus.
- Scalenus medius.
- Scalenus posticus.

9. **Muscles of the Larynx.**
- Included in the description of the Larynx.

1. **Superficial Cervical Region.**

   - **✓** Platyisma myoides.
   - **✓** Sterno-cleido-mastoid.

**Dissection.**—A block having been placed at the back of the neck, and the face turned to the side opposite that to be dissected, so as to place the parts upon the stretch, make two transverse incisions: one from the chin, along the margin of the lower jaw, to the mastoid process, and the other along the upper border of the clavicle. Connect these by an oblique incision made in the course of the Sterno-mastoid muscle, from the mastoid process to the sternum; the two flaps of integument having been removed in the direction shown in Fig. 268, the superficial fascia will be exposed.

The **Superficial Cervical Fascia** is a thin, aponeurotic lamina which is hardly demonstrable as a separate membrane. Beneath it is found the Platyisma myoides muscle.

The **Platyisma myoides** (Fig. 269) is a broad, thin plane of muscular fibres placed immediately beneath the superficial fascia on each side of the neck. It arises by thin, fibrous bands from the fascia covering the upper part of the Pectoral and Deltoid muscles; its fibres proceed obliquely upward and inward along the side of the neck. The anterior fibres interlace, in front of the jaw, with the fibres of the muscle of the opposite side; the posterior fibres pass over the lower jaw, a few of them being attached to the bone below the external oblique line, the greater number passing on to be inserted into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomatic muscles or to the margin of the Orbicularis palpebrarum. Beneath the Platyisma the external jugular vein may be seen descending from the angle of the jaw to the clavicle.

**Surgical Anatomy.**—It is essential to remember the direction of the fibres of the Platyisma in connection with the operation of bleeding from the external jugular vein; for if the point of the lancet is introduced in the direction of the muscular fibres, the orifice made will be filled up by the contraction of the muscle, and blood will not flow; but if the incision is made across the course of the fibres, they will retract and expose the orifice in the vein, and so allow the flow of blood.

**Relations.**—By its **external surface**, with the integument, to which it is united more closely below than above; by its **internal surface**, with the Pectoralis major, Deltoid, and Trapezius, and with the clavicle; in the **neck**, with the external and anterior jugular veins, the deep cervical fascia, the superficial branches of the cervical plexus, the Sterno-mastoid, Sterno-hyoid, Omo-hyoid, and Digastric muscles; behind the Sterno-mastoid muscle it covers the Scaleni muscles and the nerves of the brachial plexus; on the **face** it is in relation with the parotid gland, the facial artery and vein, and the Masseter and Buccinator muscles.

**Action.**—The Platyisma myoides produces a slight wrinkling of the surface of the skin of the neck, in an oblique direction, when the entire muscle is brought into action. Its anterior portion, the thickest part of the muscle, depresses the lower jaw; it also serves to draw down the lower lip and angle of the mouth on each side, being one of the chief agents in the expression of melancholy.

The **Deep Cervical Fascia** (Fig. 275) is a strong, fibrous layer which invests the muscles of the neck and encloses the vessels and nerves. It commences, as an extremely thin layer, at the back part of the neck, where it is attached to the
ligamentum nuchae and to the spinous process of the seventh cervical vertebrae, and, passing forward, invests the Trapezius muscle; from the anterior border of this muscle it forms a layer which covers in the posterior triangle of the neck; and, passing forward to the posterior border of the Sterno-mastoid muscle, divides into two layers, one of which passes over, and the other under, that muscle. The layer which passes over the muscle is continued forward to the front of the neck, and blends with the fascia of the opposite side, covering the anterior triangle. It is joined on its under surface, except for about an inch below, by a lamella derived from the layer covering the deep surface of the Sterno-mastoid muscle. Where these two layers do not meet a little space is left between them, as they both pass inward to the middle line of the neck. This is Burns's space, and contains a little areolar tissue and fat, and occasionally a small lymphatic gland. If traced upward, the anterior layer of the cervical fascia is found to pass across the parotid gland and Masseter muscle, forming the parotid and masseteric fasciae, and is attached to the lower border of the zygoma, and, more anteriorly, to the lower border of the body of the jaw; if traced downward, it is seen to pass to the upper border of the clavicle and sternum, being pierced just above the former bone by the external jugular vein. In the middle line of the neck the fascia is connected to the
symphysis of the inferior maxilla, and, lower down, to the hyoid bone, between which points it is thin; below the hyoid bone it becomes thicker, and is attached below to the anterior margin of the upper border of the sternum. The layer of the deep cervical fascia which passes under the Sterno-mastoid covers the anterior surface of the Scalenus anticus muscle. At the outer side of the carotid vessels it divides into two, one layer passing in front of the vessels, the other behind them. The layer which passes in front of the vessels again divides into three lamellae. Of these, the anterior lamella, except for an inch below where it forms the posterior boundary of Burns's space, joins the layer of cervical fascia passing over the Sterno-mastoid, and with it passes to the middle line covering the anterior surface of the Depressor muscles of the hyoid bone. The portion of this lamella which invests the Omo-hyoid is continued downward as a distinct process, which descends to be inserted into the sternum and cartilage of the first rib, and becomes connected with the Costo-coracoid membrane. The middle lamella passes behind the depressors of the hyoid bone and in front of the thyroid body to meet its fellow of the opposite side, in front of the trachea. At the root of the neck this middle lamella can be traced downward into the thorax to become continuous with the fibrous layer of the pericardium. The posterior lamella passes over to the inner side of the carotid vessels, and joins the layer passing behind them, thus enclosing them in a sheath. The layer of cervical fascia which passes behind the carotid vessels, having been joined by the posterior of the three lamellae from the layer of fascia passing in front of the vessels, is prolonged inward, behind the pharynx and oesophagus, forming a sheath for the Prevertebral muscles, the prevertebral fascia. The layer of the deep cervical fascia, which passes behind the Sterno-mastoid, gives off another lamella, which passes downward and outward over the brachial plexus and subclavian vessels, to assist in forming the axillary sheath. The two layers of the deep cervical fascia, where they unite opposite the angle of the lower jaw, bind the Sterno-mastoid muscle to this part of the bone. From that portion of the cervical fascia which is attached to the angle of the jaw a process of extreme density is found passing behind to the inner side of the parotid gland, to be attached to the apex of the styloid process of the temporal bone; this is termed the Styleo-maxillary liga-

The Sterno-mastoid or Sterno-cleido-mastoid (Fig. 276) is a large, thick muscle, which passes obliquely across the side of the neck, being enclosed between the two layers of the deep cervical fascia. It is thick and narrow at its central part, but is broader and thinner at each extremity. It arises, by two heads, from the sternum and clavicle. The sternal portion is a rounded fasciculus, tendinous in front, fleshy behind, which arises from the upper and anterior part of the first piece of the sternum, and is directed upward, outward, and backward. The clavicular portion arises from the inner third of the superior border of the clavicle, being composed of fleshy and aponeurotic fibres; it is directed almost vertically upward. These two portions are separated from one another, at their origin, by a triangular cellular interval, but become gradually blended, below the middle of the neck, into a thick, rounded muscle, which is inserted, by a strong tendon, into the outer surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the outer two-thirds of the superior curved line of the occipital bone. The Sterno-mastoid varies much in its extent of attachment to the clavicle; in one case the clavicular may be as narrow as the sternal portion; in another, as much as three inches in breadth. When the clavicular origin is broad it is occasionally subdivided into numerous slips separated by narrow intervals. More rarely, the corresponding margins of the Sterno-mastoid and Trapezius have been found in contact. In the application of a ligature to the third part of the subclavian artery it will be necessary, where the muscles come close together, to divide a portion of one or of both.

This muscle divides the quadrilateral space at the side of the neck into two triangles, an anterior and a posterior. The boundaries of the anterior triangle
are, in front, the median line of the neck; above, the lower border of the body of the jaw, and an imaginary line drawn from the angle of the jaw to the mastoid process; behind, the anterior border of the Sterno-mastoid muscle. The boundaries of the posterior triangle are, in front, the posterior border of the Sterno-mastoid; below, the upper border of the clavicle; behind, the anterior margin of the Trapezius.¹

**Relations.**—By its superficial surface, with the integument and Platysma, from which it is separated by the external jugular vein, the superficial branches of the cervical plexus, and the anterior layer of the deep cervical fascia. By its deep surface it is in relation with the Sterno-clavicular articulation; a process of the deep cervical fascia; the Sterno-hyoid, Sterno-thyroid, Omo-hyoid, posterior belly of the Digastric, Levator anguli scapule, Splenius and Scaleni muscles; common carotid artery, internal jugular vein, commencement of the internal and external carotid arteries, the occipital, subclavian, transversalis colli, and supra-scapular arteries and veins; the pneumogastric, hypoglossal, descendens and communicans hypoglossi nerves, and the spinal accessory nerve, which pierces its upper third; the cervical plexus, part of the parotid gland and deep lymphatic glands.

**Nerves.**—The Platysma myoides is supplied by the facial and superficial branches of the cervical plexus; the Sterno-cleido-mastoid, by the spinal accessory and deep branches of the cervical plexus.

**Actions.**—When only one Sterno-mastoid muscle acts, it flexes the head and draws it toward the shoulder of the same side, assisted by the Splenius and the Obliquis capitis inferior of the opposite side. At the same time it rotates the head so as to carry the face toward the opposite side. When both muscles are brought

¹ The anatomy of these triangles will be more exactly described with that of the vessels of the neck.
THE INFRA-HYOID REGION. 411

into action they serve to depress the head upon the neck and the neck upon the chest. If the head is fixed, they assist in elevating the thorax in forced inspiration.

Surface Form.—The anterior edge of the muscle forms a very prominent ridge beneath the skin, which it is important to notice, as it forms a guide to the surgeon in making the necessary incisions for ligation of the common carotid artery and for oesophagotomy.

Surgical Anatomy.—The relations of the sternal and clavicular parts of the Sterno-mastoid should be carefully examined, as the surgeon is sometimes required to divide one or both portions of the muscles in very-neck. One variety of this distortion is produced by spasmodic contraction or rigidity of the Sterno-mastoid; the head being carried down toward the shoulder of the same side, and the face turned to the opposite side and fixed in that position. When there is permanent shortening subcutaneous division of the muscle is resorted to. This is performed by introducing a tenotomy knife beneath it, close to its origin, and dividing it from behind forward whilst the muscle is put well upon the stretch. There is seldom any difficulty in dividing the sternal portion, by making a puncture on the inner side of the tendon, and then pushing a blunt tenotome behind it, and cutting forward. In dividing the clavicular portion care must be taken to avoid wounding the external jugular vein, which runs parallel with the posterior border of the muscle in this situation, or the anterior jugular vein, which crosses beneath it. If the external jugular vein lies near the muscle, it is safer to make the first puncture at the outer side of the tendon, and introduce a blunt tenotome from without inward. Some of the fibres of the Sterno-mastoid muscle are occasionally torn during birth, especially in breech presentations; this is accompanied by hemorrhage and formation of a swelling within the substance of the muscle. This by some is believed to be one of the causes of wry-neck.

2. Infra-hyoid Region (Figs. 276, 277).

Depressors of the Os Hyoides and Larynx.

| Sterno-hyoid. | Thyro-hyoid. |
| Sterno-thyroid. | Omo-hyoid. |

Dissection.—The muscles in this region may be exposed by removing the deep fascia from the front of the neck. In order to see the entire extent of the Omo-hyoid it is necessary to divide the Sterno-mastoid at its centre, and turn its ends aside, and to detach the Trapezius from the clavicle and scapula. This, however, should not be done until the Trapezius has been dissected.

The Sterno-hyoid is a thin, narrow, ribbon-like muscle, which arises from the inner extremity of the clavicle and the upper and posterior part of the first piece of the sternum; passing upward and inward, it is inserted, by short, tendinous fibres, into the lower border of the body of the os hyoides.—This muscle is separated, below, from its fellow by a considerable interval; but they approach one another in the middle of their course, and again diverge as they ascend. It sometimes presents, immediately above its origin, a transverse tendinous intersection, like those in the Rectus abdominis.

Relations.—By its superficial surface, below, with the sternum, the sternal end of the clavicle, and the Sterno-mastoid; and above, with the Platysma and deep cervical fascia; by its deep surface, with the Sterno-thyroid, Crico-thyroid, and Thyro-hyoid muscles, the thyroid gland, the superior thyroid vessels, the thyroid cartilage, the crico-thyroid and thyro-hyoid membranes.

The Sterno-thyroid is situated beneath the preceding muscle, but is shorter and wider than it. It arises from the posterior surface of the first bone of the sternum, below the origin of the Sterno-hyoid, and from the edge of the cartilage of the first rib, and is inserted into the oblique line on the side of the ala of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck, and is occasionally traversed by a transverse or oblique tendinous intersection, like those in the Rectus abdominis.

Relations.—By its anterior surface, with the Sterno-hyoid, Omo-hyoid, and Sterno-mastoid; by its posterior surface, from below upward, with the trachea, vena innominata, common carotid (and on the right side the arteria innominata), the thyroid gland and its vessels, and the lower part of the larynx. The middle thyroid vein lies along its inner border, a relation which it is important to remember in the operation of tracheotomy.

The Thyro-hyoid is a small, quadrilateral muscle appearing like a continuation
of the Sterno-thyroid. It arises from the oblique line on the side of the thyroid cartilage, and passes vertically upward to be inserted into the lower border of the body and greater cornu of the hyoid bone.

**Relations.**—By its external surface, with the Sterno-hyoid and Omo-hyoid muscles; by its internal surface, with the thyroid cartilage, the thyro-hyoid membrane, and the superior laryngeal vessels and nerve.

The Omo-hyoid passes across the side of the neck, from the scapula to the hyoid bone. It consists of two fleshy bellies, united by a central tendon. It arises from the upper border of the scapula close to, and occasionally from the transverse ligament which crosses, the suprascapular notch; its extent of attachment varying from a few lines to an inch. From this origin the posterior belly forms a flat, narrow fasciculus, which inclines forward and slightly upward across the lower part of the neck, behind the Sterno-mastoid muscle, where it becomes tendinous; it then changes its direction, forming an obtuse angle, and terminates in the anterior belly, which passes almost vertically upward, close to the outer border of the Sterno-hyoid, to be inserted into the lower border of the body of the os hyoides, just external to the insertion of the Sterno-hyoid. The central tendon of this muscle, which varies much in length and form, is held in position by a process of the deep cervical fascia, which includes it in a sheath. This process is prolonged down, to be attached to the cartilage of the first rib and the sternum. It is by this means that the angular form of the muscle is maintained.

This muscle subdivides each of the two large triangles at the side of the neck into two smaller triangles; the two posterior ones being the posterior superior or occipital, and the posterior inferior or subclavian; the two anterior, the anterior superior or superior carotid, and the anterior inferior or inferior carotid triangle.

**Relations.**—By its superficial surface, with the Trapezius, the Sterno-mastoid, deep cervical fascia, Platysma, and integument; by its deep surface, with the Scaleni muscles, phrenic nerve, lower cervical nerves, which go to form the brachial
plexus, the suprascapular vessels and nerve, sheath of the common carotid artery and internal jugular vein, the Sterno-thyroid and Thyro-hyoid muscles.

Nerves.—The Thyro-hyoid is supplied by the hypoglossal; the other muscles of this group by branches from the loop of communication between the descendens and communicans hypoglossi.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omo-hyoid muscles not only depress the hyoid bone, but carry it backward and to one or the other side. It is concerned especially in the act of sucking, and is also a tensor of the cervical fascia. The Thyro-hyoid may act as an elevator of the thyroid cartilage when the hyoid bone ascends, drawing upward the thyroid cartilage, behind the os hyoides.\(^1\) The Sterno-thyroid acts as a depressor of the thyroid cartilage.

3. Supra-hyoid Region (Figs. 276, 277).

**Elevators of the Os Hyoides—Depressors of the Lower Jaw.**

\[\begin{align*}
\checkmark \text{Digastric.} & \quad \checkmark \text{Mylo-hyoid.} \\
\checkmark \text{Stylo-hyoid.} & \quad \checkmark \text{Genio-hyoid.}
\end{align*}\]

**Dissection.**—To dissect these muscles a block should be placed beneath the back of the neck, and the head drawn backward and retained in that position. On the removal of the deep fascia the muscles are at once exposed.

The Digastric consists of two fleshy bellies united by an intermediate, rounded tendon. It is a small muscle, situated below the side of the body of the lower jaw, and extending, in a curved form, from the side of the head to the symphysis of the jaw. The posterior belly, longer than the anterior, arises from the digastric groove on the inner side of the mastoid process of the temporal bone, and passes downward, forward, and inward. The anterior belly arises from a depression on the inner side of the lower border of the jaw, close to the symphysis, and passes downward and backward. The two bellies terminate in the central tendon which perforates the Stylo-hyoid, and is held in connection with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, lined by a synovial membrane. A broad aponeurotic layer is given off from the tendon of the Digastric on each side, which is attached to the body and great cornu of the hyoid bone: this is termed the supra-hyoid aponeurosis. It forms a strong layer of fascia between the anterior portion of the two muscles, and a firm investment for the other muscles of the supra-hyoid region which lie deeper.

The Digastric muscle divides the anterior superior triangle of the neck into two smaller triangles; the upper, or submaxillary, being bounded, above, by the lower border of the body of the jaw, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and the Stylo-hyoid muscles; in front, by the anterior belly of the Digastric, the lower or superior carotid triangle being bounded above by the posterior belly of the Digastric, behind by the Sterno-mastoid, below by the Omo-hyoid.

**Relations.**—By its superficial surface, with the Platysma, Sterno-mastoid, part of the Splenius, Trachelo-mastoid, and Stylo-hyoid muscles, and the parotid gland. By its deep surface, the anterior belly lies on the Mylo-hyoid; the posterior belly on the Stylo-glossus, Stylo-pharyngeus, and Hyo-glossus muscles, the external carotid artery and its lingual and facial branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The Stylo-hyoid is a small, slender muscle, lying in front of, and above, the posterior belly of the Digastric. It arises from the back and outer surface of the styloid process, near the base; and, passing downward and forward, is inserted into the body of the hyoid bone, just at its junction with the greater cornu, and

\(^1\) It is this action of the Thryo-hyoid muscle which, as Dr. Buchanan has pointed out, "causes or permits the folding back of the epiglottis over the upper orifice of the larynx." *(Journal of Anat. and Phys., 2d series, No. III. p. 255).*
immediately above the Omo-hyoid. This muscle is perforated, near its insertion, by the tendon of the Digastric.

Relations.—The relations are the same as those of the posterior belly of the Digastric.

The Stylo-hyoid Ligament.—In connection with the Stylo-hyoid muscle may be described a ligamentous band, the *Stylo-hyoid ligament*. It is a fibrous cord, often containing a little cartilage in its centre, which continues the styloid process down to the hyoid bone, being attached to the tip of the former and the small cornu of the latter. It is often more or less ossified.

The Digastric and Stylo-hyoid should be removed, in order to expose the next muscle.

The Mylo-hyoid is a flat, triangular muscle, situated immediately beneath the anterior belly of the Digastric, and forming, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It arises from the whole length of the mylo-hyoid ridge, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass obliquely forward, to be inserted into the body of the os hyoides. The middle and anterior fibres are inserted into a median fibrous raphe, extending from the symphysis of the lower jaw to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. This median raphe is sometimes wanting; the muscular fibres of the two sides are then directly continuous with one another.

Relations.—By its *cutaneous surface*, with the Platysma, the anterior belly of the Digastric, the supra-hyoid aponeurosis, the submaxillary gland, submental vessels, and mylo-hyoid vessels and nerve; by its *deep or superior surface*, with the Genio-hyoid, part of the Hyo-glossus, and Stylo-glossus, muscles, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland and Wharton's duct; the sublingual and ranine vessels, and the buccal mucous membrane.

Dissection.—The Mylo-hyoid should now be removed, in order to expose the muscles which lie beneath; this is effected by detaching it from its attachments to the hyoid bone and jaw, and separating it by a vertical incision from its fellow of the opposite side.

The Genio-hyoid is a narrow, slender muscle, situated immediately beneath the inner border of the preceding. It arises from the inferior genial tubercle on the inner side of the symphysis of the jaw, and passes downward and backward, to be inserted into the anterior surface of the body of the os hyoides. This muscle lies in close contact with its fellow of the opposite side, and increases slightly in breadth as it descends.

Relations.—It is covered by the Mylo-hyoid, and lies on the Genio-hyoglossus.

Nerves.—The Digastric is supplied: its anterior belly, by the mylo-hyoid branch of the inferior dental; its posterior belly, by the facial; the Stylo-hyoid, by the facial; the Mylo-hyoid, by the mylo-hyoid branch of the inferior dental; the Genio-hyoid, by the hypoglossal.

Actions.—This group of muscles performs two very important actions. They raise the hyoid bone, and with it the base of the tongue, during the act of deglutition; or, when the hyoid bone is fixed by its depressors and those of the larynx, they depress the lower jaw. During the first act of deglutition, when the mass is being driven from the mouth into the pharynx, the hyoid bone, and with it the tongue, is carried upward and forward by the anterior belly of the Digastric, the Mylo-hyoid, and Genio-hyoid muscles. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed the hyoid bone is carried upward and backward by the posterior belly of the Digastric and Stylo-hyoid muscles, which assist in preventing the return of the morsel into the mouth.

1 This refers to the depth of the muscles from the skin in the order of dissection. In the erect position of the body each of these muscles lies above the preceding.
4. Lingual Region.

Hyo-glossus.  Palato-glossus.
Chondro-glossus.

Dissection.—After completing the dissection of the preceding muscles, saw through the lower jaw just external to the symphysis. Then draw the tongue forward, and attach it, by a stitch, to the nose; when its muscles, which are thus put on the stretch, may be examined.

The Genio-hyo-glossus has received its name from its triple attachment to the jaw, hyoid bone, and tongue, but it would be better named the Genio-glossus, since its attachment to the hyoid bone is very slight or altogether absent. It is a flat, triangular muscle, placed vertically on either side of the middle line, its apex corresponding with its point of attachment to the lower jaw, its base with its insertion into the tongue and hyoid bone. It arises by a short tendon from the superior genial tubercle on the inner side of the symphysis of the jaw, immediately above the Genio-hyoid; from this point the muscle spreads out in a fan-like form, a few of the inferior fibres passing downward, to be attached by a thin aponeurosis into the upper part of the body of the hyoid bone; the middle fibres passing backward, and the superior ones upward and forward, to enter the whole length of the under surface of the tongue, from the base to the apex. The two muscles lie on either side of the median plane; behind, they are quite distinct from each other, and are separated at their insertion into the under surface of the tongue by a tendinous raphe, which extends through the middle of the organ; in front, the two muscles are more or less blended: distinct fasciculi are to be seen passing off from one muscle, crossing the middle line, and intersecting with bundles of fibres derived from the muscle on the other side (Fig. 279).

Relations.—By its internal surface it is in contact with its fellow of the opposite
side; by its external surface, with the Inferior lingualis, the Hyo-glossus, the lingual artery and hypoglossal nerve, the lingual nerve, and sublingual gland; by its upper border, with the mucous membrane of the floor of the mouth (fratens linguae); by its lower border, with the Genio-hyoid.

The Hyo-glossus is a thin, flat, quadrilateral muscle which arises from the side of the body and whole length of the greater cornu of the hyoid bone, and passes almost vertically upward to enter the side of the tongue, between the Stylo-glossus and Lingualis. Those fibres of this muscle which arise from the body (basio-glossus) are directed upward and backward, overlapping those arising from the greater cornu (keratoglossus), which are directed upward and forward.

Relations.—By its external surface, with the Digastric, the Stylo-hyoid, Stylo-glossus, and Mylo-hyoid muscles, the submaxillary ganglion, the lingual and hypoglossal nerves, Wharton's duct, and the deep portion of the submaxillary gland; by its deep surface, with the Stylo-hyoid ligament, the Genio-hyo-glossus, Lingualis, and Middle constrictor, the lingual vessels, and the glosso-pharyngeal nerve.

The Chondro-glossus is a distinct muscular slip, about three-quarters to an inch in length, which arises from the inner side and base of the lesser cornu of the hyoid bone and contiguous portion of the body of the bone, and passes directly upward to blend with the intrinsic muscular fibres of the tongue, between the Hyoglossus and Genio-hyo-glossus. A small slip of muscular fibre is occasionally found, arising from the cartilago triticea in the thyro-hyoid ligament, and passing upward and forward to enter the tongue with the hindermost fibres of the Hyo-glossus.

The Stylo-glossus, the shortest and smallest of the three styloid muscles, arises from the anterior and outer side of the styloid process, near its apex, and from the stylo-maxillary ligament, to which its fibres, in most cases, are attached by a thin aponeurosis. Passing downward and forward between the internal and external carotid arteries, and becoming nearly horizontal in its direction, it divides upon the side of the tongue into two portions: one longitudinal, which enters the side of the tongue near its dorsal surface, blending with the fibres of the Lingualis in front of the Hyo-glossus; the other oblique, which overlaps the Hyo-glossus muscle and decussates with its fibres.

Relations.—By its external surface, from above downward, with the parotid gland, the Internal pterygoid muscle, the lingual nerve, and the mucous membrane of the mouth; by its internal surface, with the tonsil, the Superior constrictor, and the Hyo-glossus muscle.

The Palato-glossus, or Constrictor isthmi faucium, although it is one of the muscles of the tongue, serving to draw its base upward during the act of deglutition, is more nearly associated with the soft palate, both in its situation and function; it will consequently be described with that group of muscles.

Nerves.—The Palato-glossus is probably innervated by the spinal accessory nerve, through the pharyngeal plexus; the Inferior lingualis, according to some authors, by the chorda tympani; the remaining muscles of this group, by the hypoglossal.

Muscular Substance of Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets—Extrinsic and Intrinsic.
The extrinsic muscles of the tongue are those which have their origin external, and only their terminal fibres contained in the substance of the organ. They are: the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngeo-glossus). The intrinsic are those which are contained entirely within the tongue, and form the greater part of its muscular structure.

The tongue consists of symmetrical halves separated from each other in the middle line by a fibrous septum. Each half is composed of muscular fibres arranged in various directions, containing much interposed fat and supplied by vessels and nerves.

To demonstrate the various fibres of the tongue, the organ should be subjected to prolonged boiling, in order to soften the connective tissue; the dissection may then be commenced from the dorsum (Fig. 280). Immediately beneath the mucous membrane is a submucous, fibrous layer, into which the muscular fibres which terminate on the surface of the tongue are inserted. Upon removing this, with the mucous membrane, the first stratum of muscular fibres is exposed. This belongs to the group of intrinsic muscles, and has been named the Superior lingualis. It consists of a thin layer of oblique and longitudinal fibres which arise from the submucous fibrous layer, close to the Epiglottis, and from the fibrous septum, and pass forward and outward to the edges of the tongue. Between its fibres pass some vertical fibres derived from the Genio-hyo-glossus and from the vertical intrinsic muscle, which will be described later on. Beneath this layer is the second stratum of muscular fibres, derived principally from the extrinsic muscles. In front it is formed by the fibres derived from the Stylo-glossus, running along the side of the tongue, and sending one set of fibres over the dorsum which runs obliquely forward and inward to the middle line, and another set of fibres, seen at a later period of the dissection, on to the under surface of the sides of the anterior part of the tongue, which run forward and inward, between the fibres of the Hyo-glossus, to the middle line. Behind this layer of fibres, derived from the Stylo-glossus, are fibres derived from the Hyo-glossus, assisted by some few fibres of the Palato-glossus. The Hyo-glossus, entering the side of the under surface of the tongue, between the Stylo-glossus and Inferior lin-
gualis, passes round its margin and spreads out into a layer on the dorsum, which occupies the middle third of the organ, and runs almost transversely inward to the septum. It is reinforced by some fibres from the Palato-glossus; other fibres of this muscle pass more deeply and intermingle with the next layer. The posterior part of the second layer of the muscular fibres of the tongue is derived from those fibres of the Hyo-glossus which arise from the lesser cornu of the hyoid bone, and are here described as a separate muscle—the Chondro-glossus. The fibres of this muscle are arranged in a fan-shaped manner, and spread out over the posterior third of the tongue. Beneath this layer is the great mass of the intrinsic muscles of the tongue, intersected at right angles by the terminal fibres of one of the extrinsic muscles—the Genio-hyo-glossus. This portion of the tongue is paler in color and softer in texture than that already described, and is sometimes designated the medullary portion in contradistinction to the firmer superficial part, which is termed the cortical portion. It consists largely of transverse fibres, the Transverse lingualis, and of vertical fibres, the Vertical lingualis. The Transverse lingualis forms the largest portion of the third layer of muscular fibres of the tongue. The fibres arise from the median septum, and pass outward to be inserted into the submucous fibrous layer at the sides of the tongue. Intermingled with these transverse intrinsic fibres are transverse extrinsic fibres derived from the Palato-glossus and the Superior constrictor of the pharynx. These transverse extrinsic fibres, however, run in the opposite direction, passing inward, toward the septum. Intersecting the transverse fibres are a large number of vertical fibres derived partly from the Genio-hyo-glossus and partly from vertical intrinsic fibres, the Vertical lingualis. The fibres derived from the Genio-hyo-glossus enter the under surface of the tongue on each side of the median septum from base to apex. They ascend in a radiating manner to the dorsum, being inserted into the submucous fibrous layer covering the tongue on each side of the middle line. The Vertical lingualis is found only at the borders of the fore part of the tongue, external to the fibres of the Genio-hyo-glossus. Its fibres extend from the upper to the under surface of the tongue, decussating with the fibres of the other muscles, and especially with the Transverse lingualis. The fourth layer of muscular fibres of the tongue consists partly of extrinsic fibres derived from the Stylo-glossus, and partly of intrinsic fibres, the Inferior lingualis. At the sides of the under surface of the tongue are some fibres derived from the Stylo-glossus, which, as it runs forward at the side of the tongue, gives off fibres which, passing forward and inward between the fibres of the Hyo-glossus, form an inferior oblique stratum which joins in front with the anterior fibres of the Inferior lingualis. The Inferior lingualis is a longitudinal band, situated on the under surface of the tongue, lying in the interval between the Stylo-glossus, in front of the Hyo-glossus, and the Genio-hyo-glossus, and extending from the base to the apex of the organ. Posteriorly, some of the fibres are lost in the base of the tongue, and others are occasionally attached to the hyoid bone. It blends with the fibres of the Hyo-glossus, and is continued forward as far as the apex of the tongue. It is in relation by its under surface with the ranine artery.

**Surgical Anatomy.**—The fibrous septum which exists between the two halves of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free, a fact often illustrated by injecting one-half of the tongue with colored size, while the other half is left uninjected or is injected with size of a different color.

This is a point of considerable importance in connection with removal of one-half of the tongue for cancer, an operation which is now frequently resorted to when the disease is strictly confined to one side of the tongue. If the mucous membrane is divided longitudinally exactly in the middle line, the tongue can be split into halves along the median raphe without any appreciable hemorrhage, and the diseased half can then be removed.

**Actions.**—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The Genio-hyo-glossi muscles, by means of their posterior fibres, draw the base of the tongue forward, so as to protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The whole length of these
two muscles, acting along the middle line of the tongue, draw it downward, so as to make it concave from side to side, forming a channel along which fluids may pass toward the pharynx, as in sucking. The Hyo-glossi muscles depress the tongue and draw down its sides, so as to render it convex from side to side. The Stylo-glossi muscles draw the tongue upward and backward. The Palato-glossi muscles draw the base of the tongue upward. With regard to the intrinsic muscles, both the Superior and Inferior linguales tend to shorten the tongue, but the former, in addition, turn the tip and sides upward so as to render the dorsum concave, while the latter pull the tip downward and cause the dorsum to become convex. The Transverse lingualis narrows and elongates the tongue, and the Vertical lingualis flattens and broadens it. The complex arrangement of the muscular fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the various forms necessary for the enunciation of the different consonantal sounds; and Dr. Macalister states that "there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages."

Dissection (Fig. 282).—In order to examine the muscles of the pharynx, cut through the trachea and oesophagus just above the sternum, and draw them upward by dividing the loose areolar tissue connecting the pharynx with the front of the vertebral column. The parts being drawn well forward, apply the edge of the saw immediately behind the styloid processes, and saw the base of the skull through from below upward. The pharynx and mouth should then be stuffed with tow, in order to distend its cavity and render the muscles tense and easier of dissection.

The Inferior constrictor, the most superficial and thickest of the three constrictors, arises from the sides of the cricoid and thyroid cartilages. To the cricoid cartilage it is attached in the interval between the Crico-thyroid muscle in front and the articular facet for the thyroid cartilage behind. To the thyroid cartilage it is attached to the oblique line on the side of the great ala, the cartilaginous surface behind it, nearly as far as its posterior border, and to the inferior cornu. From these attachments the fibres spread backward and inward, to be inserted into the fibrous raphe in the posterior median line of the pharynx. The inferior fibres are horizontal, and continuous with the fibres of the œsophagus: the rest ascend, increasing in obliquity, and overlap the Middle constrictor. The superior laryngeal nerve and artery pass near the upper border, and the inferior, or recurrent laryngeal, beneath the lower border of this muscle, previous to their entering the larynx.

Relations.—It is covered by a dense cellular membrane which surrounds the
entire pharynx. Behind, it is in relation with the vertebral column and the Longus colli muscle; laterally, with the thyroid gland, the common carotid artery, and the Sterno-thyroid muscle; by its internal surface, with the Middle constrictor, the Stylo-pharyngeus, Palato-pharyngeus, the fibrous coat and mucous membrane of the pharynx.

The Middle constrictor is a flattened, fan-shaped muscle, smaller than the preceding. It arises from the whole length of the upper surface of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylo-hyoid ligament. The fibres diverge from their origin, the lower ones descending beneath the Inferior constrictor, the middle fibres passing transversely, and the upper fibres ascending and overlapping the Superior constrictor. The muscle is inserted into the posterior median fibrous raphe, blending in the middle line with the one of the opposite side.

Relations.—This muscle is separated from the Superior constrictor by the glosso-pharyngeal nerve and the Stylo-pharyngeus muscle, and from the Inferior constrictor by the superior laryngeal nerve. Behind, it lies on the vertebral column, the Longus colli, and the Rectus capitis anticus major. On each side it is in relation with the carotid vessels, the pharyngeal plexus, and some lymphatic glands. Near its origin it is covered by the Hyo-glossus, from which it is separated by the lingual vessels. It lies upon the Superior constrictor, the Stylo-pharyngeus, the Palato-pharyngeus, the fibrous coat, and the mucous membrane of the pharynx.

The Superior Constrictor is a quadrilateral muscle, thinner and paler than the other constrictors, and situated at the upper part of the pharynx. It arises from the lower third of the posterior margin of the internal pterygoid plate and its hamular process, from the contiguous portion of the palate bone and the reflected tendon of the Tensor palati muscle, from the pterygo-maxillary ligament, from the alveolar process above the posterior extremity of the mylo-hyoid ridge, and by a few fibres from the side of the tongue. From these points the fibres curve backward, to be inserted into the median raphe, being also prolonged by means of a fibrous aponeurosis to the pharyngeal spine on the basilar process of the occipital bone. The superior fibres arch beneath the Levator palati and the Eustachian tube, the interval between the upper border of the muscle and the basilar process being deficient in muscular fibres and closed by fibrous membrane. This interval is known as the sinus of Morgagni.

Relations.—By its outer surface, with the vertebral column, the internal carotid artery, the internal jugular vein, the glosso-pharyngeal, pneumogastric, spinal accessory, hypoglossal, and sympathetic nerves, the Middle constrictor, which overlaps it, and the Stylo-pharyngeus; by its internal surface, with the Palato-pharyngeus, the tonsil, the fibrous coat and mucous membrane of the pharynx.

The Stylo-pharyngeus is a long, slender muscle, round above, broad and thin below. It arises from the inner side of the base of the styloid process, passes downward along the side of the pharynx between the Superior and Middle constrictors, and spreads out beneath the mucous membrane, where some of its fibres are lost in the Constrictor muscles; and others, joining with the Palato-pharyngeus, are inserted into the posterior border of the thyroid cartilage. The glosso-pharyngeal nerve runs on the outer side of this muscle, and crosses over it in passing forward to the tongue.

Relations.—Externally, with the Stylo-glossus muscle, the parotid gland, the external carotid artery, and the Middle constrictor; internally, with the internal carotid, the internal jugular vein, the Superior constrictor, Palato-pharyngeus, and mucous membrane.

Nerves.—The Constrictors are supplied by branches from the pharyngeal plexus, the Stylo-pharyngeus by the glosso-pharyngeal nerve, and the Inferior constrictor by an additional branch from the external laryngeal nerve and by the recurrent laryngeal.

Actions.—When deglutition is about to be performed, the pharynx is drawn
upward and dilated in different directions, to receive the morsel propelled into it from the mouth. The Stylo-pharyngei, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upward and outward, and so increase its transverse diameter, its breadth in the antero-posterior direction being increased by the larynx and tongue being carried forward in their ascent. As soon as the morsel is received in the pharynx, the Elevator muscles relax, the bag descends, and the Constrictors contract upon the morsel, and convey it gradually downward into the oesophagus. Besides its action in deglutition, the pharynx also exerts an important influence in the modulation of the voice, especially in the production of the higher tones.

6. Palatal Region.

| Levator palati. | Palato-glossus. |
| Tensor palati.  | Palato-pharyngeus. |
| Azygos uvulæ.  | Salpingo-pharyngeus. |

Dissection (Fig. 283).—Lay open the pharynx from behind by a vertical incision extending from its upper to its lower part, and partially divide the occipital attachment by a transverse incision on each side of the vertical one; the posterior surface of the soft palate is then exposed. Having fixed the uvula so as to make it tense, the mucous membrane and glands should be carefully removed from the posterior surface of the soft palate, and the muscles of this part are at once exposed.

The Levator palati is a long, thick, rounded muscle, placed on the outer side of the posterior nares. It arises from the under surface of the apex of the petrous portion of the temporal bone, and from the adjoining cartilaginous portion of the Eustachian tube; after passing into the pharynx, above the upper concave margin

![Figure 283: Muscles of the soft palate, the pharynx being laid open from behind.](image-url)
of the Superior constrictor, it passes obliquely downward and inward, its fibres spreading out in the soft palate as far as the middle line, where they blend with those of the opposite side.

**Relations.**—*Externally*, with the Tensor palati and Superior constrictor; *internally*, with the mucous membrane of the pharynx; *posteriorly*, with the posterior fasciculus of the Palato-pharyngeus, the Azygos uvulae, and the mucous lining of the soft palate.

The Circumflexus or Tensor palati is a broad, thin, ribbon-like muscle, placed on the outer side of the Levator palati, and consisting of a vertical and a horizontal portion. The vertical portion arises by a broad, thin, and flat lamella from the sphenoid fossa at the base of the internal pterygoid plate; from the spine of the sphenoid; the vaginal process of the temporal bone and the anterior aspect of the cartilaginous portion of the Eustachian tube: descending vertically between the internal pterygoid plate and the inner surface of the Internal pterygoid muscle, it terminates in a tendon, which winds round the hamular process, being retained in this situation by some of the fibres of origin of the Internal pterygoid muscle, and lubricated by a bursa. The tendon or horizontal portion then passes horizontally inward, and is inserted into a broad aponeurosis, the palatine aponeurosis, and into the transverse ridge on the horizontal portion of the palate bone.

**Relations.**—*Externally*, with the Internal pterygoid; *internally*, with the Levator palati, from which it is separated by the Superior constrictor, and with the internal pterygoid plate. In the soft palate its tendon and the palatine aponeurosis is anterior to that of the Levator palati, being covered by the Palato-glossus and the mucous membrane.

**Palatine Aponeurosis.**—Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella which supports the muscles and gives strength to the soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally, it is continuous with the pharyngeal aponeurosis.

The Azygos uvula is not a single muscle, as would be inferred from its name, but a pair of narrow cylindrical fleshy fasciculi placed side by side in the median line of the soft palate. Each muscle arises from the posterior nasal spine of the palate bone and from the contiguous tendinous aponeurosis of the soft palate, and descends to be inserted into the uvula.

**Relations.**—*Anteriorly*, with the tendinous expansion of the Levatores palati; *behind*, with the posterior fasciculus of the Palato-pharyngeus and the mucous membrane.

The two next muscles are exposed by removing the mucous membrane from the pillars of the soft palate throughout nearly their whole extent.

The Palato-glossus (Constrictor isthmi faucium) is a small fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the soft palate. It arises from the anterior surface of the soft palate on each side of the uvula, and, passing downward, forward, and outward in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transversus linguae. In the soft palate the fibres of this muscle are continuous with those of the muscle of the opposite side.

The Palato-pharyngeus is a long, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the posterior pillar of the soft palate. It is separated from the Palato-glossus by an angular interval, in which the tonsil is lodged. It arises from the soft palate by an expanded fasciculus, which is divided into two parts by the Levator palati and Azygos uvulae. The posterior fasciculus lies in contact with the mucous membrane, and also joins with the corresponding muscle in the middle line; the anterior fasciculus, the thicker, lies in the soft palate between the Levator and Tensor, and
joins in the middle line the corresponding part of the opposite muscle. Passing outward and downward behind the tonsil, the Palato-pharyngeus joins the Stylo- pharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly to decussate with the muscle of the opposite side.

The Salpingo-pharyngeus.—This muscle arises from the inferior part of the Eustachian tube near its orifice; it passes downward and blends with the posterior fasciculus of the Palato-pharyngeus.

Relations.—In the soft palate its posterior surface is covered by mucous membrane, from which it is separated by a layer of palatine glands. By its anterior surface it is in relation with the Tensor palati. Where it forms the posterior pillar of the fauces it is covered by mucous membrane, excepting on its outer surface. In the pharynx it lies between the mucous membrane and the Constrictor muscles.

In a dissection of the soft palate from its posterior or nasal surface to its anterior or oral surface, the muscles would be exposed in the following order: viz. the posterior fasciculus of the Palato-pharyngeus, covered over by the mucous membrane reflected from the floor of the nasal fossa; the Azygos uvulae; the Levator palati; the anterior fasciculus of the Palato-pharyngeus; the aponeurosis of the Tensor palati, and the Palato-glossus covered over by a reflection from the oral mucous membrane.

Nerves.—The Tensor palati is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the internal branch of the spinal accessory, whose fibres are distributed along with certain branches of the pneumogastric through the pharyngeal plexus.1

Actions.—During the first stage of deglutition the morsel of food is driven back into the fauces by the pressure of the tongue against the hard palate, the base of the tongue being, at the same time, retracted, and the larynx raised with the pharynx, and carried forward under it. During the second stage the epiglottis is pressed over the superior aperture of the larynx, and the morsel glides past it; then the Palato-glossus muscles, the constrictors of the fauces, contract behind the food; the soft palate is slightly raised by the Levator palati, and made tense by the Tensor palati; and the Palato-pharyngei, by their contraction, pull the pharynx upward over the morsel of food, and at the same time come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented passing into the upper part of the pharynx or the posterior nares; at the same time the latter muscles form an inclined plane, directed obliquely downward and backward, along the under surface of which the morsel descends into the lower part of the pharynx. The Salpingo-pharyngeus raises the upper and lateral part of the pharynx—i.e. that part which is above the point where the Stylo-pharyngeus is attached to the pharynx.

Surgical Anatomy.—The muscles of the soft palate should be carefully dissected, the relations they bear to the surrounding parts especially examined, and their action attentively studied upon the dead subject, as the surgeon is required to divide one or more of these muscles in the operation of staphylorrhaphy. Sir W. Fergusson was the first to show that in the congenital deficiency called cleft palate the edges of the fissure are forcibly separated by the action of the Levatores palati and Palato-pharyngei muscles, producing very considerable impediment to the healing process after the performance of the operation for uniting their margins by adhesion; he, consequently, recommended the division of these muscles as one of the most important steps in the operation. This he effected by an incision made with a curved knife introduced behind the soft palate. The incision is to be halfway between the hamular process and Eustachian tube, and perpendicular to a line drawn between them. This incision perfectly accomplishes the division of the Levator palati. The Palato-pharyngeus may be divided by cutting across the posterior pillar of the soft palate, just below the tonsil, with a pair of blunt-pointed curved scissors; and the anterior pillar may be divided also. To divide the Levator palati the plan recommended by Mr. Pollock is to be greatly preferred. The soft palate being put upon the stretch, a double-edged knife is passed through it just on the inner side of the hamular process

and above the line of the Levator palati. The handle being now alternately raised and depressed, a sweeping cut is made along the posterior surface of the soft palate, and the knife withdrawn, leaving only a small opening in the mucous membrane on the anterior surface. If this operation is performed on the dead body and the parts afterward dissected, the Levator palati will be found completely divided. In the present day, however, this division of the muscles, as part of the operation of staphylorraphy, is not so much insisted upon. All tension is prevented by making longitudinal incisions on either side, parallel to the cleft and just internal to the hamular process, in such a position as to avoid the posterior palatine artery.

7. Anterior Vertebral Region.

Rectus capitis anticus major. Rectus capitis lateralis.
Rectus capitis anticus minor. Longus colli.

The **Rectus capitis anticus major** (Fig. 284), broad and thick above, narrow below, appears like a continuation upward of the Scalenus anticus. It arises by

![Fig. 284.—The prevertebral muscles.](image)

four tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and ascends, converging toward its fellow of the opposite side, to be inserted into the basilar process of the occipital bone.

**Relations.**—By its *anterior surface*, with the pharynx, the sympathetic nerve, and the sheath enclosing the internal and common carotid artery, internal jugular vein, and pneumogastric nerve; by its *posterior surface*, with the Longus colli, the Rectus capitis anticus minor, and the upper cervical vertebrae.

The **Rectus capitis anticus minor** is a short, flat muscle, situated immediately behind the upper part of the preceding. It arises from the anterior surface of the lateral mass of the atlas and from the root of its transverse process, and, passing
obliquely upward and inward, is inserted into the basilar process immediately behind the preceding muscle.

**Relations.**—By its anterior surface, with the Rectus capitis anticus major; by its posterior surface, with the front of the occipito-atlantal articulation.

The *Rectus capitis lateralis* is a short, flat muscle, which arises from the upper surface of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone.

**Relations.**—By its anterior surface, with the internal jugular vein; by its posterior surface, with the vertebral artery. On its outer side lies the occipital artery; on its inner side, the suboccipital nerve.

The *Longus colli* is a long, flat muscle, situated on the anterior surface of the spine, between the atlas and the third dorsal vertebra. It is broad in the middle, narrow and pointed at each extremity, and consists of three portions: a superior, oblique, an inferior oblique, and a vertical portion. The *superior oblique portion* arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebrae, and, ascending obliquely inward, is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas. The *inferior oblique portion*, the smallest part of the muscle, arises from the front of the bodies of the first two or three dorsal vertebrae, and, ascending obliquely outward, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The *vertical portion* lies directly on the front of the spine; it arises, below, from the front of the bodies of the upper three dorsal and lower three cervical vertebrae, and is inserted above into the front of the bodies of the second, third, and fourth cervical vertebrae above.

**Relations.**—By its anterior surface, with the pharynx, the oesophagus, sympathetic nerve, the sheath of the great vessels of the neck, the inferior thyroid artery, and recurrent laryngeal nerve; by its posterior surface, with the cervical and dorsal portions of the spine. Its *inner border* is separated from the opposite muscle by a considerable interval below, but they approach each other above.

### 8. Lateral Vertebral Region.

**Scalenus anticus.**

**Scalenus medius.**

**Scalenus posticus.**

The *Scalenus anticus* is a conical-shaped muscle, situated deeply at the side of the neck, behind the Sterno-mastoid. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and, descending almost vertically, is inserted by a narrow, flat tendon into the impression on the inner border and upper surface of the first rib. The lower part of this muscle separates the subclavian artery and vein, the latter being in front, and the former, with the brachial plexus, behind.

**Relations.**—In front, with the clavicle, the Subclavius, Sterno-mastoid, and Omo-hyoid muscles, the transversalis colli, the suprascapular and ascending cervical arteries, the subclavian vein, and the phrenic nerve; by its *posterior surface*, with the Scalenus medius, pleura, the subclavian artery, and brachial plexus of nerves. It is separated from the Longus colli, on the inner side, by the vertebral artery. On the anterior tubercles of the transverse processes of the cervical vertebrae, between the attachments of the Scalenus anticus and Longus colli, lies the ascending cervical branch of the inferior thyroid artery.

The *Scalenus medius*, the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical vertebrae, and, descending along the side of the vertebral column, is inserted by a broad attachment into the upper surface of the first rib, behind the groove for the subclavian artery, as far back as the tubercle. It is separated from the Scalenus anticus by a subclavian artery below and the cervical nerves above. The posterior thoracic, or nerve of Bell, is formed in the substance of the Scalenus medius and emerges from it.
Relations.—By its anterior surface, with the Sterno-mastoid; it is crossed by the clavicle, the Omo-hyoid muscle, subclavian artery, and the cervical nerves. To its outer side is the Levator anguli scapulae and the Scalenum posticus muscle.

The Scalenum posticus, the smallest of the three Scaleni, arises, by two or three separate tendons, from the posterior tubercles of the transverse processes of the lower two or three cervical vertebrae, and, diminishing as it descends, is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the Serratus magnus. This is the most deeply placed of the three Scaleni, and is occasionally blended with the Scalenum medius.

Nerves.—The Rectus capitis anticus major and minor and the Rectus lateralis are supplied by the first cervical nerve, and from the loop formed between it and the second; the Longus colli and Scaleni, by branches from the anterior divisions of the lower cervical nerves (fifth, sixth, seventh, and eighth) before they form the brachial plexus. The Scalenum medius also receives a filament from the deep external branches of the cervical plexus.

Actions.—The Rectus anticus major and minor are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural position after it has been drawn backward. These muscles also serve to flex the head, and,
from their obliquity, rotate it, so as to turn the face to one or the other side. The Longus colli flexes and slightly rotates the cervical portion of the spine. The Scaleni muscles, when they take their fixed point from above, elevate the first and second ribs, and are, therefore, inspiratory muscles. When they take their fixed point from below, they bend the spinal column to one or the other side. If the muscles of both sides act, lateral movement is prevented, but the spine is slightly flexed. The Rectus lateralis, acting on one side, bends the head laterally.

**Surface Form.**—The muscles in the neck, with the exception of the Platysma myoides, are invested by the deep cervical fascia, which softens down their form, and is of considerable importance in connection with deep cervical abscesses and tumors, modifying the direction of their growth and causing them to extend laterally instead of toward the surface. The Platysma myoides does not influence surface form except it is in action, when it produces wrinkling of the skin of the neck, which is thrown into oblique ridges parallel with the fasciculi of the muscle. Sometimes this contraction takes place suddenly and repeatedly as a sort of spasmodic twitching, the result of a nervous habit. The Sterno-cleido-mastoid is the most important muscle of the neck as regards its surface form. If the muscle is put into action by drawing the chin downward and to the opposite shoulder, its surface form will be plainly outlined. The sternal origin will stand out as a sharply-defined ridge, while the clavicular origin will present a flatter and not so prominent an outline. The fleshy middle portion will appear as an oblique roll or elevation, with a thick rounded anterior border gradually becoming less marked above. On the opposite side—i.e., on the side to which the head is turned—the outline is lost, its place being occupied by an oblique groove in the integument. When the muscle is at rest its anterior border is still visible, forming an oblique rounded ridge, terminating below in the sharp outline of the sternal head. The posterior border of the muscle does not show above the clavicular head. The anterior border is defined by drawing a line from the tip of the mastoid process to the sternoclavicular joint. It is an important surface-marking in the operation of ligation of the common carotid artery and some other operations. Between the sternal and clavicular heads is a slight depression, most marked when the muscle is in action. This is bounded below by the prominent sternal extremity of the clavicle. Between the sternal origins of the two muscles is a V-shaped space, the suprasternal notch, more pronounced below, and becoming toned down above, where the Sterno-hyoid and Sterno-thyroid muscles, lying upon the trachea, become more prominent. Above the hyoid bone, in the middle line, the anterior belly of the Diaphragm to a certain extent influences surface form. It corresponds to a line drawn from the symphysis of the lower jaw to the side of the body of the hyoid bone, and renders this part of the hyo-mental region convex. In the posterior triangle of the neck, the posterior belly of the Omo-hyoid, when in action, forms a conspicuous object, especially in thin necks, presenting a cord-like form running across this region, almost parallel with, and a little above, the clavicle.

**MUSCLES AND FASCIAE OF THE TRUNK.**

The muscles of the Trunk may be arranged in four groups: the muscles of the Back, of the Thorax, of the Abdomen, and of the Perineum.

**THE BACK.**

The muscles of the Back are very numerous, and may be subdivided into five layers.

**First Layer.**

Trapezius.
Latissimus dorsi.

**Second Layer.**

levator anguli scapulae.
Rhomboideus minor.
Rhomboideus major.

**Third Layer.**

Serratus posticus superior.
Serratus posticus inferior.
Splenius capitis.
Splenius colli.

**Fourth Layer.**

Sacral and Lumbar Regions.
Erector spine.

Dorsal Region.

Ilio-costalis.
Musculus accessorius ad ilio-costalem.
Longissimus dorsi.
Spinalis dorsi.

Cervical Region.

Cervicalis ascendens.
Transversalis colli.
Dissection (Fig. 286).—Place the body in a prone position, with the arms extended over the sides of the table, and the chest and abdomen supported by several blocks, so as to render the muscles tense. Then make an incision along the middle line of the back from the occipital protuberance to the coccyx. Make a transverse incision from the upper end of this to the mastoid process, and a third incision from its lower end, along the crest of the ilium to about its middle. This large intervening space should, for convenience of dissection, be subdivided by a fourth incision, extending obliquely from the spinous process of the last dorsal vertebra, upward and outward, to the acromion process. This incision corresponds with the lower border of the Trapezius muscle. The flaps of integument are then to be removed in the direction shown in the figure.

The superficial fascia is exposed upon removing the skin from the back. It forms a layer of considerable thickness and strength, in which a quantity of granular pinkish fat is contained. It is continuous with the superficial fascia in other parts of the body. The deep fascia is a dense fibrous layer attached to the occipital bone, the spines of the vertebrae, the crest of the ilium, and the spine of the scapula. It covers over the superficial muscles, forming sheaths for them, and is continuous, in the neck at the anterior border of the Trapezius, with the deep cervical fascia; on the thorax, with the deep fascia of the axilla and chest, and on the abdomen with the fascia covering the abdominal muscles.

The Trapezius (Fig. 287) is a broad, flat, triangular muscle, placed immediately beneath the skin and fascia, and covering the upper and back part of the neck and shoulders. It arises from the inner third of the superior curved line of the occipital bone; from the ligamentum nuchae, the spinous process of the seventh cervical, and those of all the dorsal vertebrae; and from the corresponding portion of the supraspinous ligament. From this origin the superior fibres proceed downward and outward, the inferior ones upward and outward, and the middle fibres horizontally, and are inserted, the superior ones into the outer third of the posterior border of the clavicle; the middle fibres into the inner margin of the acromion process, and into the superior lip of the posterior border or crest of the spine of the scapula; the inferior fibres converge near the scapula, and terminate in a triangular aponeurosis, which glides over a smooth surface at the inner extremity of the spine, to be inserted into a tubercle at the outer part of this smooth surface. The Trapezius is fleshy in the greater part of its extent, but tendinous at its origin.
OF THE BACK.

Fig. 287. — Muscles of the back. On the left side is exposed the first layer; on the right side, the second layer and part of the third.

and insertion. At its occipital origin it is connected to the bone by a thin fibrous lamina, firmly adherent to the skin, and wanting the lustrous, shining appearance
of aponeuroses. At its origin from the spines of the vertebrae it is connected to
the bones by means of a broad semi-elliptical aponeurosis, which occupies the
space between the sixth cervical and the third dorsal vertebra, and forms, with
the aponeurosis of the opposite muscle, a tendinous ellipse. The rest of the muscle
arises by numerous short tendinous fibres. If the Trapezius is dissected on both
sides, the two muscles resemble a trapezium or diamond-shaped quadrangle; two
angles corresponding to the shoulders; a third to the occipital protuberance;
and the fourth to the spinous process of the last dorsal vertebra.

The clavicular insertion of this muscle varies as to the extent of its attach-
ment; it sometimes advances as far as the middle of the clavicle, and may even
become blended with the posterior edge of the Sterno-mastoid or overlap it. This
should be borne in mind in the operation for tying the third part of the subclavian
artery.

Relations.—By its superficial surface, with the integument; by its deep
surface, in the neck, with the Complexus, Splenius, Levator anguli scapulae, and
Rhomboides minor; in the back, with the Rhomboideus major, Supraspinatus,
Infraspinatus, and Vertebral aponeurosis (which separates it from the prolongations
of the Erector spinae), and the Latissimus dorsi. The spinal accessory nerve and
the superficial cervical artery pass beneath the anterior border of this muscle,
near the clavicle. The anterior margin of its cervical portion forms the posterior
boundary of the posterior triangle of the neck, the other boundaries being the Sterno-
mastoid in front and the clavicle below.

The Ligamentum nuchae (Fig. 287) is a thin band of condensed cellulo-fibrous
membrane placed in the line of union between the two Trapezi and in the neck. It
extends from the external occipital protuberance to the spinous process of the
seventh cervical vertebra, where it is continuous with the supraspinous ligament.
From its anterior surface a fleshy lamina is given off, which is attached to the
spinous process of each of the cervical vertebrae, excepting the atlas, so as to form
a septum between the muscles on each side of the neck. In man it is merely the
rudiment of an important elastic ligament which, in some of the lower animals,
serves to sustain the weight of the head.

The Latissimus dorsi is a broad flat muscle which covers the lumbar and
the lower half of the dorsal regions, and is gradually contracted into a narrow
fasciculus at its insertion into the humerus. It arises by an aponeurosis from the
spinous processes of the six inferior dorsal, from those of the lumbar and sacral
vertebrae, and from the supraspinous ligament. Over the sacrum the aponeurosis
of this muscle blends with the posterior layer of the lumbar fascia. It also arises
from the external lip of the crest of the ilium, behind the origin of the External
oblique, and by fleshy digitations from the three or four lower ribs, which are
interposed between similar processes of the External oblique muscle (Fig. 292,
page 449). From this extensive origin the fibres pass in different directions, the
upper ones horizontally, the middle obliquely upward, and the lower vertically
upward, so as to converge and form a thick fasciculus, which crosses the inferior
angle of the scapula, and occasionally receives a few fibres from it. The muscle
then curves around the lower border of the Teres major, and is twisted upon itself,
so that the superior fibres become at first posterior and then inferior, and the
vertical fibres at first anterior and then superior. It then terminates in a short
quadrilateral tendon, about three inches in length, which, passing in front of the
tendon of the Teres major, is inserted into the bottom of the bicipital groove of
the humerus, its insertion extending higher on the humerus than that of the
tendon of the Pectoralis major. The lower border of the tendon of this muscle is
united with that of the Teres major, the surfaces of the two being separated by a
bursa; another bursa is sometimes interposed between the muscle and the inferior
angle of the scapula. This muscle at its insertion gives off an expansion to the
deep fascia of the arm.

A muscular slip, varying from 3 to 4 inches in length, and from 1⁄4 to 3⁄4 of an inch in breadth,
ocasionally arises from the upper edge of the Latissimus dorsi about the middle of the posterior
fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coraco-brachialis, or the fascia over the Biceps. The position of this abnormal slip is a point of interest in its relation to the axillary artery, as it crosses the vessel just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It may be easily recognized by the transverse direction of its fibres. Dr. Struther found it, in 8 out of 103 subjects, occurring seven times on both sides.

**Relations.**—Its superficial surface is subcutaneous, excepting at its upper part, where it is covered by the Trapezius, and at its insertion, where its tendon is crossed by the axillary vessels and the brachial plexus of nerves. By its deep surface it is in relation with the Lumbar fascia, the Serratus posterior inferior, the lower external intercostal muscles and ribs, inferior angle of the scapula, Rhomboideus major, Infraspinatus, and Teres major. Its outer margin is separated below from the External oblique by a small triangular interval; and another triangular interval exists between its upper border and the margin of the Trapezius, in which the Rhomboideus major muscle is exposed.

**Nerves.**—The Trapezius is supplied by the spinal accessory, and by branches from the anterior divisions of the third and fourth cervical nerves: the Latissimus dorsi, by the middle or long subscapular nerve.

### Second Layer.

- **Levator anguli scapulae.**
- **Rhomboideus minor.**
- **Rhomboideus major.**

**Dissection.**—The Trapezius must be removed, in order to expose the next layer; to effect this, detach the muscle from its attachment to the clavicle and spine of the scapula, and turn it back toward the spine.

The **Levator anguli scapulae** is situated at the back part and side of the neck. It arises by tendinous slips from the posterior tubercles of the transverse processes of the four upper cervical vertebrae; these, becoming fleshy, are united so as to form a flat muscle, which, passing downward and backward, is inserted into the posterior border of the scapula, between the superior angle and the triangular smooth surface at the root of the spine.

**Relations.**—By its superficial surface, with the integument, Trapezius, and Sterno-mastoid; by its deep surface, with the Splenius colli, Transversalis colli, Cervicalis ascendenis, and Serratus posticus superior muscles, and with the Transversalis colli and posterior scapular arteries.

The **Rhomboideus minor** arises from the ligamentum nuchae and spinous processes of the seventh cervical and first dorsal vertebrae. Passing downward and outward, it is inserted into the margin of the triangular smooth surface at the root of the spine of the scapula. This small muscle is usually separated from the Rhomboideus major by a slight cellular interval.

**Relations.**—By its superficial (posterior) surface, with the Trapezius; by its deep surface, with the same structures as the Rhomboideus major.

The **Rhomboideus major** is situated immediately below the preceding, the adjacent margins of the two being occasionally united. It arises by tendinous fibres from the spinous processes of the four or five upper dorsal vertebrae and the supraspinous ligament, and is inserted into a narrow tendinous arch attached above to the lower part of the triangular surface at the root of the spine; below, to the inferior angle, the arch being connected to the border of the scapula by a thin membrane. When the arch extends, as it occasionally does, but a short distance, the muscular fibres are inserted into the scapula itself.

**Relations.**—By its superficial (posterior) surface, with the Latissimus dorsi; by its deep (anterior) surface, with the Serratus posticus superior, posterior scapular artery, the vertebral aponeurosis which separates it from the prolongations from the Erector spinae, the Intercostal muscles, and ribs.

**Nerves.**—The Rhomboid muscles are supplied by branches from the anterior-
division of the fifth cervical nerve; the Levator anguli scapulae, by the anterior
division of the third and fourth cervical nerves.

Actions.—The movements effected by the preceding muscles are numerous, as
may be conceived from their extensive attachment. The whole of the Trapezius
when in action retracts the scapula and rotates it on a sagittal axis; if the head is
fixed, the upper part of the Trapezius will elevate the point of the shoulder, as in
supporting weights; when the lower fibres are brought into action, they assist in
depressing the bone. If the scapula is prevented from gliding on the chest, the
middle and lower fibres of the muscle cause it to rotate, so that the aeromion is
raised. If the shoulders are fixed, both Trapezius, acting together, will draw the
head directly backward; or if only one acts, the head is drawn to the corresponding
side.

The Latissimus dorsi, when it acts upon the humerus, draws it backward,
adducts, and at the same time rotates it inward. It is the muscle which is
principally employed in giving a downward blow, as in felling a tree or in sabre
practice. If the arm is fixed, the muscle may act in various ways upon the trunk;
thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms
are fixed, the two muscles may assist the Abdominal and great Pectoral muscles in
suspending and drawing the whole trunk forward, as in climbing or walking on
crutches.

The Levator anguli scapulae raises the superior angle of the scapula, assisting
the Trapezius in bearing weights or in shrugging the shoulders. If the shoulder
be fixed, the Levator anguli scapulae inclines the neck to the corresponding side
and rotates it in the same direction. The Rhomboid muscles carry the inferior
angle backward and upward, thus producing a slight rotation of the scapula upon
the side of the chest, the Rhomboideus major acting especially on the lower angle
of the scapula through the tendinous arch by which it is inserted. The Rhomboid
muscles, acting together with the middle and inferior fibres of the Trapezius, will
draw the scapula directly backward toward the spine.

Third Layer.

Serratus posticus superior. Serratus posticus inferior.

Splenius \{ Splenius capitis.
Splenius \{ Splenius colli.

Dissection.—To bring into view the third layer of muscles, remove the whole of the second,
together with the Latissimus dorsi, by cutting through the Levator anguli scapulae and Rhom-
boideus near their insertion, and reflecting them upward, and by dividing the Latissimus
dorsi in the middle by a vertical incision carried from its upper to its lower part, and reflecting
the two halves of the muscle.

The Serratus posticus superior is a thin, flat, quadrilateral muscle situated at
the upper and back part of the thorax. It arises by a thin and broad aponeurosis
from the ligamentum nuchae, and from the spinous processes of the last cervical
and two or three upper dorsal vertebrae and from the supraspinous ligament.
Inclining downward and outward, it becomes muscular, and is inserted, by four
fleshy digitations into the upper borders of the second, third, fourth, and fifth ribs,
a little beyond their angles.

Relations.—By its superficial surface, with the Trapezius, Rhomboidei, and
Levator anguli scapulae; by its deep surface, with the Splenius and the vertebral
aponeurosis, which separates it from the prolongations of the Erector spinæ,
and with the Intercostal muscles and ribs.

The Serratus posticus inferior is situated at the junction of the dorsal and lumbar
regions; it is of an irregularly quadrilateral form, broader than the preceding,
and separated from it by a considerable interval. It arises by a thin aponeurosis
from the spinous processes of the last two dorsal and two or three upper lumbar
vertebrae, and from the supraspinous ligaments. Passing obliquely upward
and outward, it becomes fleshy, and divides into four flat digitations, which are
inserted into the lower borders of the four lower ribs, a little beyond their angles.
The thin aponeurosis of origin is intimately blended with the tendon of origin of the Latissimus dorsi muscle and with the lumbar fascia (posterior layer).

**Relations.**—By its superficial surface, with the Latissimus dorsi, with the aponeurosis of which its own aponeurotic origin is inseparably blended; by its deep surface, the Erector spinae, ribs, and Intercostal muscles. Its upper margin is continuous with the vertebral aponeurosis.

The Vertebral aponeurosis is a thin, fibrous lamina extending along the whole length of the back part of the thoracic region, serving to bind down the long extensor muscles of the back which support the spine and head, and separate them from those muscles which connect the spine to the upper extremity. It consists of longitudinal and transverse fibres blended together, forming a thin lamella, which is attached in the median line to the spinous processes of the dorsal vertebrae; externally, to the angles of the ribs; and below, to the aponeurosis of the Serratus posticus inferior and tendon of origin of the Latissimus dorsi, with both of which it is continuous; above, it passes beneath the Serratus posticus superior, and blends with the deep fascia of the neck.

The Lumbar fascia (Figs. 287 and 295) occupies the interval between the last rib and crest of the ilium. It is attached internally to the spinous process of the lumbar and sacral vertebrae; above, to the last rib and to the cartilage of the eleventh rib; below, to the posterior third of the crest of the ilium. The posterior layer of this fascia blends with, and is practically the same thing as, the aponeurosis of the Latissimus dorsi and Serratus posticus inferior. It gives attachment to the Internal oblique muscle of the abdomen. The anterior or deep surface gives off two layers: one lies between the Erector spinae and Quadratus lumborum, and is attached to the tips of the transverse processes of the lumbar vertebrae (posterior aponeurosis of the Transversalis muscle); the other lies on the anterior or internal surface of the Quadratus lumborum, and is attached to the front part of the same transverse processes (transversalis fascia). The upper portion of this layer, which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the ligamentum arcaatum externum. Therefore these three layers of the lumbar fascia form two spaces: between the posterior and middle layer is situated the Erector spinae and the Multifidus spinae; between the middle and anterior layers is situated the Quadratus lumborum.

Now detach the Serratus posticus superior from its origin, and turn it outward, when the Splenius muscle will be brought into view.

The Splenius is situated at the back of the neck and upper part of the dorsal region. At its origin it is a single muscle, narrow, and pointed in form; but it soon becomes broader, and divides into two portions, which have separate insertions. It arises, by tendinous fibres, from the lower half of the ligamentum nuchae, from the spinous processes of the last cervical and of the six upper dorsal vertebrae, and from the supraspinous ligament. From this origin the fleshy fibres proceed obliquely upward and outward, forming a broad flat muscle, which divides as it ascends into two portions, the Splenius capitis and Splenius colli.

The Splenius capitis is inserted into the mastoid process of the temporal bone, and into the rough surface on the occipital bone just beneath the superior curved line.

The Splenius colli is inserted, by tendinous fasciculi, into the posterior tubercles of the transverse processes of the two or three upper cervical vertebrae. The Splenius is separated from its fellow of the opposite side by a triangular interval, in which is seen the Complexus.

**Relations.**—By its superficial surface, with the Trapezius, from which it is separated below by the Rhomboidei and the Serratus posticus superior. It is covered at its insertion by the Sterno-mastoid, and at the lower and back part of the neck by the Levator anguli scapulae; by its deep surface, with the Spinalis dorsi, Longissimus dorsi, Semispinalis colli, Complexus, Trachelo-mastoid, and Transversalis colli.
Nerves.—The Splenius is supplied from the external branches of the posterior divisions of the cervical nerves; the Serratus posticus superior is supplied by the external branches of the posterior divisions of the upper dorsal nerves; the Serratus posticus inferior by the external branches of the posterior divisions of the lower dorsal nerves.

Actions.—The Serrati are respiratory muscles. The Serratus posticus superior elevates the ribs; it is therefore an inspiratory muscle; while the Serratus inferior draws the lower ribs downward and backward, and thus elongates the thorax. It also fixes the lower ribs, thus aiding the downward action of the diaphragm and resisting the tendency which it has to draw the lower ribs upward and forward. It must therefore be regarded as a muscle of inspiration. This muscle is also probably a tensor of the vertebral aponeurosis. The Splenii muscles of the two sides, acting together, draw the head directly backward, assisting the Trapezius and Complexus; acting separately, they draw the head to one or the other side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

Ilio-costalis.

Musculus accessorius ad ilio-costalem.

Longissimus dorsi.

Spinalis dorsi.

Cervical Region.

Cervicalis ascendens.

Transversalis colli.

Trachelo-mastoid.

Complexus.

Biventer cervicis.

Spinalis colli.

Dissection.—To expose the muscles of the fourth layer, remove entirely the Serrati and the vertebral and lumbar fasciae. Then detach the Splenius by separating its attachment to the spinous processes and reflecting it outward.

The Erector spinae (Fig. 288) and its prolongations in the dorsal and cervical regions fill up the vertebral groove on each side of the spine. It is covered in the lumbar region by the lumbar fascia; in the dorsal region, by the Serrati muscles and the vertebral aponeurosis; and in the cervical region, by a layer of cervical fascia continued beneath the Trapezius and the Splenius. This large muscular and tendinous mass varies in size and structure at different parts of the spine. In the sacral region the Erector spinae is narrow and pointed, and its origin chiefly tendinous in structure. In the lumbar region the muscle becomes enlarged, and forms a large fleshy mass. In the dorsal region it subdivides into two parts, which gradually diminish in size as they ascend to be inserted into the vertebral and ribs. In the cervical region it is gradually lost, where a number of small muscles are continued upward to the head to support it upon the spine.

The Erector spinae arises from the sacro-iliac groove, and from the anterior surface of a very broad and thick tendon, which is attached, internally, to the spines of the sacrum, to the spinous processes of the lumbar vertebrae, and the supraspinous ligament; externally, to the back part of the inner lip of the crest of the ilium, and to the series of eminences on the posterior part of the sacrum, which represents the transverse processes, where it blends with the great sacro-sciatic ligament. The muscular fibres form a single large fleshy mass, bounded in front by the transverse processes of the lumbar vertebrae and by the middle lamella of the lumbar fascia. Opposite the last rib it divides into two parts, the Ilio-costalis and the Longissimus dorsi.

The Ilio-costalis (Sacro-lumbalis), the external and smaller portion of the Erector spinae, is inserted, generally, by six or seven flattened tendons into the angles of the six or seven lower ribs. The number of the tendons of this muscle is, however, very variable, and therefore the number of ribs into which it is inserted. Frequently it is found to possess nine or ten tendons, and sometimes as many tendons as there are ribs, and is then inserted into the angles of all the ribs.
If this muscle is reflected outward, it will be seen to be reinforced by a series of muscular slips which arise from the angles of the ribs; by means of these the Ilio-
costalis is continued upward to the upper ribs and cervical portion of the spine. The accessory portions form two additional muscles, the Musculus accessorius and the Cervicalis ascendens.

The **Musculus accessorius ad ilio-costalem** arises, by separate flattened tendons, from the angles of the six lower ribs; these become muscular, and are finally inserted, by separate tendons, into the angles of the six upper ribs.

The **Cervicalis ascendens** is the continuation of the Accessorius upward into the neck; it is situated on the inner side of the tendons of the Accessorius, arising from the angles of the four or five upper ribs, and is inserted by a series of slender tendons into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebrae.

The **Longissimus dorsi** is the inner and larger portion of the Erector spinae. In the lumbar region, where it is as yet blended with the Ilio-costalis, some of the fibres are attached to the whole length of the posterior surface of the transverse processes of the lumbar vertebrae, to the tubercles at the back of the articular processes, and to the middle layer of the lumbar fascia. In the dorsal region the Longissimus dorsi is inserted, by long thin tendons, into the tips of the transverse processes of all the dorsal vertebrae, and into from seven to eleven of the lower ribs between their tubercles and angles. This muscle is continued upward, to the cranium and cervical portion of the spine, by means of two additional muscles, the Transversalis colli and Trachelo-mastoid.

The **Transversalis colli** (or cervicis), placed on the inner side of the Longissimus dorsi, arises by long thin tendons from the summits of the transverse processes of the six upper dorsal vertebrae, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebrae from the second to the sixth.

The **Trachelo-mastoid** lies on the inner side of the preceding, between it and the Complexus muscle. It arises, by four tendons, from the transverse processes of the third, fourth, fifth, and sixth dorsal vertebrae, and by additional separate tendons from the articular processes of the three or four lower cervical. The fibres form a small muscle, which ascends to be inserted into the posterior margin of the mastoid process, beneath the Splenius and Sterno-mastoid muscles. This small muscle is almost always crossed by a tendinous intersection near its insertion into the mastoid process.²

**Relations.**—The Erector spinae and its prolongations are bound down to the vertebrae and ribs in the lumbar and dorsal regions by the lumbar fascia and the vertebral aponeurosis. The inner part of these muscles covers the muscles of the fifth layer. In the neck they are in relation, by their superficial surface, with the Trapezius and Splenius; by their deep surface, with the Semispinalis dorsi et colli and the Recti and Obliqui.

The **Spinalis dorsi** connects the spinous processes of the upper lumbar and the dorsal vertebrae together by a series of muscular and tendinous slips which are intimately blended with the Longissimus dorsi. It is situated at the inner side of the Longissimus dorsi, arising, by three or four tendons, from the spinous processes of the first two lumbar and the last two dorsal vertebrae: these, uniting, form a small muscle, which is inserted, by separate tendons, into the spinous processes of the dorsal vertebrae, the number varying from four to eight. It is intimately united with the Semispinalis dorsi, which lies beneath it.

The **Spinalis colli** is a small muscle, connecting together the spinous processes of the cervical vertebrae, and analogous to the Spinalis dorsi in the dorsal region. It varies considerably in its size and in its extent of attachment to the vertebrae, not only in different bodies, but on the two sides of the same body. It usually arises by fleshy or tendinous slips, varying from two to four in number, from the

---

¹ This muscle is sometimes called "Cervicalis descendens." The student should remember that these long muscles take their fixed point from above or from below according to circumstances.

² These two muscles are sometimes described as one, having a common origin, but dividing above at their insertion. The Trachelo-mastoid is then termed the Transversalis capitis.
spinous processes of the fifth, sixth, and seventh cervical vertebrae, and occasionally from the first and second dorsal, and is inserted into the spinous process of the axis, and occasionally into the spinous processes of the two vertebrae below it. This muscle was found absent in five cases out of twenty-four.

The Complexus is a broad thick muscle, situated at the upper and back part of the neck, beneath the Splenius, and internal to the Transversalis colli and Trachelo-mastoid. It arises, by a series of tendons, about seven in number, from the tips of the transverse processes of the upper three dorsal and seventh cervical vertebrae, and from the articular processes of the three cervical above this. The tendons, uniting, form a broad muscle, which passes obliquely upward and inward, and is inserted into the innermost depression between the two curved lines of the occipital bone. This muscle, about its middle, is traversed by a transverse tendinous intersection.

The Biventer cervicis is a small fasciculus, situated on the inner side of the preceding, and in the majority of cases blended with it; it has received its name from having a tendon intervening between two fleshy bellies. It is sometimes described as a separate muscle, arising, by from two to four tendinous slips, from the transverse processes of as many of the upper dorsal vertebrae, and inserted, on the inner side of the Complexus, into the superior curved line of the occipital bone.

Relations.—The Complexus is covered by the Splenius and the Trapezius. It lies on the Rectus capitis posticus major and minor, the Obliquus capitis superior and inferior, and on the Semispinalis colli, from which it is separated by the profund a cervicis artery, the princeps cervicis artery, and branches of the posterior cervical plexus of nerves. The Biventer cervicis is separated from its fellow of the opposite side by the ligamentum nuchae...

Nerves.—The Erector spinae and its subdivisions in the dorsal region are supplied by the external branches of the posterior divisions of the lumbar and dorsal nerves, while its subdivisions in the cervical region, the Transversalis colli and Trachelo-mastoid, are supplied by the external branches of the posterior divisions of the cervical nerves; the Complexus, by the internal branches of the posterior divisions of the cervical nerves, the suboccipital and great occipital. The Spinalis colli is supplied by the internal branches of the posterior divisions of the cervical nerves; and the Spinalis dorsi, by the internal branches of the posterior divisions of the dorsal nerves.

Fifth Layer.

Semispinalis dorsi.  Extensor coccygis.
Semispinalis colli.  Intertransversales.
Multifidus spine.  Rectus capitis posticus major.
Rotatores spine.  Rectus capitis posticus minor.
Supraspinales.  Obliquus capitis superior.
Interspinales.  Obliquus capitis inferior.

Dissection.—Remove the muscles of the preceding layer by dividing and turning aside the Complexus; then detach the Spinalis and Longissimus dorsi from their attachments, divide the Erector spinae at its connection below to the sacral and lumbar spines, and turn it outward. The muscles filling up the interval between the spinous and transverse processes are then exposed.

The Semispinalis dorsi (Fig. 288) consists of thin, narrow, fleshy fasciculi interposed between tendons of considerable length. It arises by a series of small tendons from the transverse processes of the lower dorsal vertebrae, from the tenth or eleventh to the fifth or sixth; and is inserted, by five or six tendons, into the spinous processes of the upper four dorsal and lower two cervical vertebrae.

The Semispinalis colli, thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper four dorsal vertebrae and from the articular processes of the lower four cervical vertebrae; and is inserted into the spinous processes of four cervical vertebrae, from the axis to the
fifth cervical. The fasciculus connected with the axis is the largest, and chiefly muscular in structure.

**Relations.**—By their superficial surface, from below upward, with the Spinalis dorsi, Longissimus dorsi, Splenius, Complexus, the profunda cervicis artery, the princeps cervicis artery, and the internal branches of the posterior divisions of the first, second, and third cervical nerves; by their deep surface, with the Multifidus spine.

The Multifidus spine consists of a number of fleshy and tendinous fasciculi which fill up the groove on either side of the spinous processes of the vertebrae, from the sacrum to the axis. In the sacral region these fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, and from the aponeurosis of origin of the Erector spinae; in the iliac region, from the inner surface of the posterior superior spine of the ilium and posterior sacro-iliac ligaments; in the lumbar regions, from the articular processes; in the dorsal region, from the transverse processes; and in the cervical region, from the articular processes. Each fasciculus, passing obliquely upward and inward, is inserted into the lamina and whole length of the spinous process of one of the vertebrae above. These fasciculi vary in length: the most superficial, the longest, pass from one vertebra to the third or fourth above; those next in order pass from one vertebra to the second or third above; whilst the deepest connect two contiguous vertebrae.

**Relations.**—By its superficial surface, with the Longissimus dorsi, Spinalis dorsi, Semispinalis dorsi, and Semispinalis colli; by its deep surface, with the laminae and spinous processes of the vertebrae, and with the Rotatores spine in the dorsal region.

The Rotatores spine are found only in the dorsal region of the spine, beneath the Multifidus spine; they are eleven in number on each side. Each muscle is small and somewhat quadrilateral in form; it arises from the upper and back part of the transverse process, and is inserted into the lower border and outer surface of the lamina of the vertebra above, the fibres extending as far inward as the root of the spinous process. The first is found between the first and second dorsal; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end.

The Supraspinales consist of a series of fleshy bands which lie on the spinous processes in the cervical region of the spine.

The Interspinales are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebrae, one on each side of the interspinous ligament. In the cervical region they are most distinct, and consist of six pairs, the first being situated between the axis and third vertebra, and the last between the last cervical and the first dorsal. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the dorsal region they are found between the first and second vertebrae, and occasionally between the second and third; and below, between the eleventh and twelfth. In the lumbar region there are four pairs of these muscles in the intervals between the five lumbar vertebrae. There is also occasionally one in the interspinous space, between the last dorsal and first lumbar, and between the fifth lumbar and the sacrum.

The Extensor coccygis is a slender muscular fasciculus, occasionally present, which extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last bone of the sacrum or first piece of the coccyx, and passes downward to be inserted into the lower part of the coccyx. It is a rudiment of the Extensor muscle of the caudal vertebra which exists in some animals.

The Intertransversales are small muscles placed between the transverse processes of the vertebrae. In the cervical region they are most developed, consisting of rounded muscular and tendinous fasciculi, which are placed in pairs, passing between the two anterior and the two posterior tubercles of the transverse processes
of two contiguous vertebrae, separated from one another by the anterior division of the cervical nerve, which lies in the groove between them. In this region there are seven pairs of these muscles, the first pair being between the atlas and axis, and the last pair between the seventh cervical and first dorsal vertebrae. In the dorsal region they are least developed, consisting chiefly of rounded tendinous cords in the intertransverse spaces of the upper dorsal vertebrae; but between the transverse processes of the lower three dorsal vertebrae, and between the transverse processes of the last dorsal and the first lumbar, they are muscular in structure. In the lumbar region they are four in number, and consist of a single muscular layer, which occupies the entire interspace between the transverse processes of the lower lumbar vertebrae, whilst those between the transverse processes of the upper lumbar are not attached to more than half the breadth of the process.

The Rectus capitis posticus major arises by a pointed tendinous origin from the spinous process of the axis, and, becoming broader as it ascends, is inserted into the inferior curved line of the occipital bone and the surface of bone immediately below it. As the muscles of the two sides pass upward and outward, they leave between them a triangular space, in which are seen the Recti capitis postici minores muscles.

Relations.—By its superficial surface, with the Complexus, and, at its insertion, with the Superior oblique; by its deep surface, with part of the Rectus capitis posticus minor, the posterior arch of the atlas, the posterior occipito-atlantal ligament, and part of the occipital bone.

The Rectus capitis posticus minor, the smallest of the four muscles in this region, is of a triangular shape; it arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, becoming broader as it ascends, is inserted into the rough surface beneath the inferior curved line, nearly as far as the foramen magnum, nearer to the middle line than the preceding.

Relations.—By its superficial surface, with the Complexus and the Rectus capitis posticus major; by its deep surface, with the posterior occipito-atlantal ligament.

The Obliquis capitis inferior, the larger of the two Oblique muscles, arises from the apex of the spinous process of the axis, and passes almost horizontally outward, to be inserted into the lower and back part of the transverse process of the atlas.

Relations.—By its superficial surface, with the Complexus and with the posterior division of the second cervical nerve, which crosses it; by its deep surface, with the vertebral artery and posterior atlanto-axial ligament.

The Obliquis capitis superior, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the preceding, and, passing obliquely upward and inward, is inserted into the occipital bone, between the two curved lines, external to the Complexus.

Relations.—By its superficial surface, with the Complexus and Trachelo-mastoid. By its deep surface, with the posterior occipito-atlantal ligament.

The Suboccipital Triangle.—Between the two oblique muscles and the Rectus capitis posticus major a triangular interval exists, the suboccipital triangle. This triangle is bounded, above and internally, by the Rectus capitis posticus major; above and externally, by the Obliquis capitis superior; below and externally, by the Obliquis capitis inferior. It is covered in by a layer of dense fibro-fatty tissue, situated beneath the Complexus muscle. The floor is formed by the posterior occipito-atlantal ligament, the posterior arch of the atlas, and the posterior atlanto-axial ligament. It contains the vertebral artery, as it runs in a deep groove on the upper surface of the posterior arch of the atlas, and the posterior division of the suboccipital nerve.

Nerves.—The Semispinalis dorsi and Rotatores spinae are supplied by the internal branches of the posterior divisions of the dorsal nerves; the Semispinalis colli, by the internal branches of the posterior divisions of the cervical nerves; the
Supraspinales and Interspinales are supplied by the internal branches of the posterior divisions of the cervical, dorsal, and lumbar nerves in the respective regions; the Intertransversales, by the internal branches of the posterior divisions of the cervical, dorsal, and lumbar nerves; the Multifidus spinae, by the same, with the addition of the internal branches of the posterior divisions of the sacral nerves. The Recti and Obliqui muscles are all supplied by the suboccipital nerve; the Inferior oblique is also supplied by the great occipital nerve.

**Actions.**—When both the Spinales dorsi contract, they extend the dorsal region of the spine; when only one muscle contracts, it helps to bend the dorsal portion of the spine to one side. The Erector spinae, comprising the Ilio-costalis and the Longissimus dorsi with their accessory muscles, serves, as its name implies, to maintain the spine in the erect posture; it also serves to bend the trunk backward when it is required to counterbalance the influence of any weight at the front of the body, as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distension, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the spine being drawn backward by the counterbalancing action of the Erector spinae muscles. The muscles which form the continuation of the Erector spinae upward steady the head and neck, and fix them in the upright position. If the Ilio-costalis and Longissimus dorsi of one side act, they serve to draw down the chest and spine to the corresponding side. The Cervicales ascendens, taking their fixed points from the cervical vertebrae, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. The Transversalis colli, when both muscles act, taking their fixed point from below, bend the neck backward. The Tracheolomastoid, when both muscles act, taking their fixed point from below, bend the head backward; while, if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two Recti muscles draw the head backward. The Rectus capitis posticus major, owing to its obliquity, rotates the cranium, with the atlas, round the odontoid process, turning the face to the same side. The Multifidus spinae acts successively upon the different parts of the spine; thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; these then become the fixed points for the fasciculi moving the dorsal region, and so on throughout the entire length of the spine; it is by the successive contraction and relaxation of the separate fasciculi of this and other muscles that the spine preserves the erect posture without the fatigue that would necessarily have been produced had this position been maintained by the action of a single muscle. The Multifidus spinae, besides preserving the erect position of the spine, serves to rotate it, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the Obliquus externus abdominis. The Complexi draw the head directly backward: if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The Superior oblique draws the head backward, and, from the obliquity in the direction of its fibres, will slightly rotate the cranium, turning the face to the opposite side. The Obliquus capitis inferior rotates the atlas, and with it the cranium, round the odontoid process, turning the face to the same side. The Semispinales, when the muscles of the two sides act together, help to extend the spine; when the muscles of one side only act, they rotate the dorsal and cervical parts of the spine, turning the body to the opposite side. The Supraspinales and Interspinales by approximating the spinous processes help to extend the spine. The Intertransversales approximate the transverse processes, and help to bend the spine to one side. The Rotatores spinae assist the Multifidus spinae to rotate the spine, so that the front of the trunk is turned to the side opposite to that from which the muscle acts.

**Surface Forms.**—The surface forms produced by the muscles of the back are numerous and difficult to analyze unless they are considered in systematic order. The most superficial layer,
consisting of large strata of muscular substance, influences to a certain extent the surface form, and at the same time reveals the forms of the layers beneath. The Trapezius at the upper part of the back, and in the neck, covers over and softens down the outline of the underlying muscles. Its anterior border forms the posterior boundary of the posterior triangle of the neck. It forms a slight undulating ridge which passes downward and forward from the occiput to the junction of the middle and outer third of the clavicle. The tendinous ellipse formed by a part of the origin of the two muscles at the back of the neck is always to be seen as an oval depression, more marked when the muscle is in action. A slight dimple on the skin opposite the interval between the spinous processes of the third and fourth dorsal vertebrae marks the triangular aponeurosis by which the inferior fibres are inserted into the root of the spine of the scapula. From this point the inferior border of the muscle may be traced as an undulating ridge to the spinous process of the twelfth dorsal vertebra. In like manner, the Lattissimus dorsi softens down and modulates the underlying structures at the lower part of the back and lower part of the side of the chest. In this way it modulates the outline of the Erector spinae; of the Serratus posterior inferior, which is sometimes to be discerned through it, and is sometimes entirely obscured by it; of part of the Serratus magnus and Superior oblique, which it covers; and of the convex oblique ridges formed by the ribs with the intervening intercostal spaces. The anterior border of the muscle is the only part which gives a distinct surface form. This border may be traced, when the muscle is in action, as a rounded edge, starting from the crest of the ilium, and passing obliquely forward and upward to the posterior border of the axilla, where it combines with the Teres major in forming a thick rounded fold, the posterior boundary of the axillary space. The muscles in the second layer influence to a very considerable extent the surface form of the back of the neck and upper part of the trunk. The Levator anguli scapulae reveals itself as a prominent divergent line, running downward and outward, from the transverse processes of the upper cervical vertebrae to the angle of the scapula, covered over and toned down by the overlying Trapezius. The Rhomboideus procerus, when in action, a vertical eminence between the internal border of the scapula and the spinal furrow, varying in intensity according to the condition of contraction or relaxation of the Trapezius muscle, by which they are for the most part covered. The lowermost part of the Rhomboideus major is uncovered by the Trapezius, and forms on the surface an oblique ridge running upward and inward from the inferior angle of the scapula. Of the muscles of the third layer of the back, the Serratus posticus superior does not in any way influence surface form. The Serratus posticus inferior, when in strong action, may occasionally be revealed as an elevation beneath the Latissimus dorsi. The Splenius by their divergence serve to broaden out the upper part of the back of the neck and produce a local fulness in this situation, but do not otherwise influence surface form. Beneath all these muscles those of the fourth layer—the Erector spinae and its continuations—influence the surface form in a decided manner. In the loins, the Erector spinae, bound down by the lumbar fascia, forms a rounded vertical eminence, which determines the depth of the spinal furrow, and which below tapers to a point on the posterior surface of the sacrum and becomes lost there. In the back it forms a flattened plane which gradually becomes lost. In the neck the only part of this group of muscles which influences surface form is the Tracheo-mastoid, which produces a short convergent line across the upper part of the posterior triangle of the neck, appearing from under cover of the posterior border of the Sterno-mastoid and being lost below beneath the Trapezius.

THE THORAX.

The Muscles exclusively connected with the bones in this region are few in number. They are the

Intercostales externi. Infra costales.

Intercostales interni. Triangularis sterni.

Levatores costarum.

Intercostal Fasciae.—A thin but firm layer of fascia covers the outer surface of the External intercostal and the inner surface of the Internal intercostal muscles; and a third layer, the middle intercostal fascia, more delicate, is interposed between the two planes of muscular fibres. These are the intercostal fasciae; they are best marked in those situations where the muscular fibres are deficient, as between the External intercostal muscles and sternum, in front, and between the Internal intercostals and spine, behind.

The Intercostal muscles (Fig. 299) are two thin planes of muscular and tendinous fibres, placed one over the other, filling up the intercostal spaces, and being directed obliquely between the margins of the adjacent ribs. They have received the name “external” and “internal” from the position they bear to one another. The tendinous fibres are longer and more numerous than the muscular; hence the walls of the intercostal spaces possess very considerable strength, to which the crossing of the muscular fibres materially contributes.
The **External Intercostals** are eleven in number on each side. They extend from the tubercles of the ribs, behind, to the commencement of the cartilages of the ribs, in front, where they terminate in a thin membranous aponeurosis, which is continued forward to the sternum. They arise from the lower border of each rib, and are inserted into the upper border of the rib below. In the two lowest spaces they extend to the end of the cartilages. Their fibres are directed obliquely downward and forward, in a similar direction with those of the External oblique muscle of the abdomen. They are thicker than the Internal intercostals.

**Relations.**—By their *outer surface*, with the muscles which immediately invest the chest—viz. the Pectoralis major and minor, Serratus magnus, and Rhomboideus major, Serratus posticus superior and inferior, Scalenus posticus, Ilio-costalis, Longissimus dorsi, Cervicalis ascendens, Transversalis colli, Levatores costarum, and the Obliquus externus abdominis; by their *internal surface*, with the middle intercostal fascia, which separates them from the intercostal vessels and nerve, and the Internal intercostal muscles, and, behind, from the pleura.

The **Internal intercostals** are also eleven in number on each side. They commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and from the anterior extremities of the cartilages of the false ribs, and extend backward as far as the angles of the ribs, whence they are continued to the vertebral column by a thin aponeurosis. They arise from the ridge on the inner surface of each rib, as well as from the corresponding costal cartilage, and are inserted into the upper border of the rib below. Their fibres are directed obliquely downward and backward, passing in the opposite direction to the fibres of the External intercostal muscle.

**Relations.**—By their *external surface*, with the intercostal vessels and nerves, and the middle intercostal fascia, which separates them from the External intercostal muscles; by their *internal surface*, with the internal intercostal fascia, which separates them from the pleura costalis, Triangularis sterni, and Diaphragm.

The **Infracostales** (subcostales) consist of muscular and aponeurotic fasciculi, which vary in number and length: they are placed on the inner surface of the ribs, where the Internal intercostal muscles cease; they arise from the inner surface of one rib, and are inserted into the inner surface of the first, second, or third rib below. Their direction is most usually oblique, like the Internal intercostals. They are most frequent between the lower ribs.

The **Triangularis sterni** is a thin plane of muscular and tendinous fibres, situated upon the inner wall of the front of the chest. It arises from the lower part of the side of the sternum, from the inner surface of the ensiform cartilage, and from the sternal ends of the costal cartilages of the three or four lower true ribs. Its fibres diverge upward and outward, to be inserted by fleshy digitations into the lower border and inner surfaces of the costal cartilages of the second, third, fourth, and fifth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the Transversalis; those which succeed are oblique, whilst the superior fibres are almost vertical. This muscle varies much in its attachment, not only in different bodies, but on opposite sides of the same body.

**Relations.**—*In front*, with the sternum, ensiform cartilage, costal cartilages, Internal intercostal muscles, and internal mammary vessels; *behind*, with the pleura, pericardium, and anterior mediastinum.

The **Levatores Costarum** (Fig. 288), twelve in number on each side, are small tendinous and fleshy bundles, which arise from the extremities of the transverse processes of the seventh cervical and eleven upper dorsal vertebrae, and, passing obliquely downward and outward, are inserted into the upper border of the rib below them, between the tubercle and the angle. That for the first rib arises from the transverse process of the last cervical vertebra, and that for the last from the eleventh dorsal. The Inferior levatores divide into two fasciculi, one of which is inserted as above described; the other fasciculus passes down to the second rib.
below its origin; thus, each of the lower ribs receives fibres from the transverse processes of two vertebrae.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

Actions.—The Intercostals are the chief agents in the movement of the ribs in ordinary respiration. When the first rib is elevated and fixed by the Scaleni, the External intercostals raise the other ribs, especially their fore part, and so increase the capacity of the chest from before backward; at the same time they evert their lower borders, and so enlarge the thoracic cavity transversely. The Internal intercostals, at the side of the thorax, depress the ribs and invert their lower borders, and so diminish the thoracic cavity; but at the fore part of the chest these muscles assist the External intercostals in raising the cartilages. The Levatores

1 The view of the action of the Intercostal muscles given in the text is that which is taught by Hutchinson (Cyl. of Anat. and Phys., art. "Thorax"), and is usually adopted in our schools. It is, however, much disputed. Hamberger believed that the External intercostals act as elevators of the ribs, or muscles of inspiration, while the Internal act in expiration. Haller taught that both sets of muscles act in common—viz. as muscles of inspiration—and this view is adopted by many of the best anatomists of the Continent, and appears supported by many observations made on the human subject under various conditions of disease, and on living animals after the muscles have been exposed under chloroform. The reader may consult an interesting paper by Dr. Cleland in the Journal of Anat. and Phys. No. 11, May, 1867, p. 209, "On the Hutchinsonian Theory of the Action of the Intercostal Muscles," who refers also to Henle, Luschka, Budge, and Baumler, Observations on the Action of the Intercostal Muscles, Erlangen, 1860. (In New Syd. Soc.'s Year-Book for 1861, p. 69.) Dr. W. W. Keen has come to the conclusion, from experiments made upon a criminal executed by hanging, that the Exter-
costarum assist the External intercostals in raising the ribs. The Triangularis sterni draws down the costal cartilages; it is therefore an expiratory muscle.

**Muscles of Inspiration and Expiration.**—The muscles which assist the action of the Diaphragm in ordinary tranquil inspiration are the Intercostals and the Levatores costarum, as above stated, and the Scaleni. When the need for more forcible action exists, the shoulders and the base of the scapula are fixed, and then the powerful muscles of forced inspiration come into play; the chief of these are the Trapezius, the Pectoralis, the Serratus posticus superior and inferior, and the Rhomboidei. The lower fibres of the Serratus magnus may possibly assist slightly in dilating the chest by raising and evertting the ribs. The Sterno-mastoid also, when the head is fixed, assists in forced inspiration by drawing up the sternum and by fixing the clavicle, and thus affording a fixed point for the action of the muscles of the chest. The Iliocostalis and Quadratus lumborum assist in forced inspiration by fixing the last rib (see page 458).

The ordinary action of expiration is hardly effected by muscular force, but results from a return of the walls of the thorax to a condition of rest, owing to their own elasticity and to that of the lungs. Forced expiratory actions are performed mainly by the flat muscles (Obliqui and Transversalis) of the abdomen, assisted also by the Rectus. Other muscles of forced expiration are possibly the Internal intercostals and Triangularis sterni (as above mentioned), and the Iliocostalis.

**THE DIAPHRAGMATIC REGION.**

**Diaphragm.**

The **Diaphragm** (διάφραγμα, a partition wall) (Fig. 290) is a thin musculo-fibrous septum, placed obliquely at the junction of the upper with the middle third of the trunk, and separating the thorax from the abdomen, forming the floor of the former cavity and the roof of the latter. It is elliptical, its longest diameter being from side to side, somewhat fan-shaped, the broad elliptical portion being horizontal, the narrow part, which represents the handle of the fan, vertical, and joined at right angles to the former. It is from this circumstance that some anatomists describe it as consisting of two portions, the upper or great muscle of the Diaphragm, and the lower or lesser muscle. It arises from the whole of the internal circumference of the thorax; being attached, in front, by fleshy fibres to the ensiform cartilage; on either side, to the inner surface of the cartilages and bony portions of the six or seven inferior ribs, interdigitating with the Transversalis; and behind, to two aponeurotic arches, named the ligamentum arcuatum externum and internum, and to the lumbar vertebrae. The fibres from these sources vary in length; those arising from the ensiform appendix are very short and occasionally aponeurotic; those from the ligamenta arcuata, and more especially those from the cartilages of the ribs at the side of the chest, are longer, describe well-marked curves as they ascend, and finally converge to be inserted into the circumference of the central tendon. Between the sides of the muscular slip from the ensiform appendix and the cartilages of the adjoining ribs the fibres of the Diaphragm are deficient, the interval being filled by areolar tissue, covered on the thoracic side by the pleura; on the abdominal, by the peritoneum. This is, consequently, a weak point, and a portion of the contents of the abdomen may protrude into the chest, forming phrenic or diaphragmatic hernia, or a collection of pus in the mediastinum may descend through it, so as to point at the epigastrium.

The **ligamentum arcuatum internum** is a tendinous arch, thrown across the upper part of the Psoas magnus muscle, on each side of the spine. It is connected, by one end, to the outer side of the body of the first lumbar vertebra, being continuous with the outer side of the tendon of the corresponding crus; and, by nal intercostals are muscles of expiration, as they pulled the ribs down, while the Internal intercostals pulled the ribs up and are muscles of inspiration (Trans. Col. Phys. Philadelphia, Third Series, vol. i., 1875, p. 97).
the other end, to the front of the transverse process of the first, and sometimes also to that of the second, lumbar vertebra.

The ligamentum arcuatum externum is the thickened upper margin of the anterior lamella of the lumbar fascia; it arches across the upper part of the Quadratus lumborum, being attached, by one extremity, to the front of the transverse process of the first, sometimes also of the second, lumbar vertebra, and, by the other, to the apex and lower margin of the last rib.

The Crura.—The Diaphragm is connected to the spine by two crura or pillars, which are situated on the bodies of the lumbar vertebrae, on each side of the aorta. The crura, at their origin, are tendinous in structure; the right crus, larger and longer than the left, arising from the anterior surface of the bodies and intervertebral substances of the three or four upper lumbar vertebrae; the left, from

![Diagram of the Diaphragm](image-url)

**Fig. 250.—The Diaphragm. Under surface.**

the two upper; both blending with the anterior common ligament of the spine. These tendinous portions of the crura pass forward and inward, and gradually converge to meet in the middle line, forming an arch, beneath which passes the aorta, vena azygos major, and thoracic duct. From this tendinous arch muscular fibres arise, which diverge, the outermost portion being directed upward and outward to the central tendon; the innermost decussating in front of the aorta, and then diverging, so as to surround the oesophagus before ending in the central tendon. The fibres derived from the right crus are the most numerous and pass in front of those derived from the left.

The Central or Cordiform Tendon of the Diaphragm is a thin but strong tendinous aponeurosis, situated at the centre of the vault formed by the muscle, immediately below the pericardium, with which its upper surface is blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions, or leaflets,
separated from one another by slight indentations. The right leaflet is the largest: the middle one, directed toward the ensiform cartilage, the next in size; and the left, the smallest. In structure, the tendon is composed of several planes of fibres, which intersect one another at various angles, and unite into straight or curved bundles—an arrangement which affords it additional strength.

The *Openings* connected with the Diaphragm are three large and several smaller apertures. The former are the aortic, the oesophageal, and the opening for the vena cava.

The *aortic opening* is the lowest and the most posterior of the three large apertures connected with this muscle. It is situated in the middle line, immediately in front of the bodies of the vertebrae; and is, therefore, *behind* the Diaphragm, not in it. It is an osseo-aponeurotic aperture, formed by a tendinous arch thrown across the front of the bodies of the vertebrae, from the crus on one side to that on the other, and transmits the aorta, vena azygos major, thoracic duct, and sometimes the left sympathetic nerve. Occasionally some tendinous fibres are prolonged across the bodies of the vertebrae from the inner part of the lower end of the crura, passing behind the aorta, and thus converting the opening into a fibrous ring.

The *oesophageal opening*, elliptical in form, muscular in structure, and formed by the two crura, is placed above, and, at the same time, anterior, and a little to the left of, the preceding. It transmits the oesophagus and pneumogastric nerves. The anterior margin of this aperture is occasionally tendinous, being formed by the margin of the central tendon.

The *opening for the vena cava* (*foramen quadratum*) is the highest; it is quadrilateral in form, tendinous in structure, and placed at the junction of the right and middle leaflets of the central tendon, its margins being bounded by four bundles of tendinous fibres, which meet at right angles.

The *right crus* transmits the sympathetic and the greater and lesser splanchnic nerves of the right side; the *left crus*, the greater and lesser splanchnic nerves of the left side and the vena azygos minor.

The *Serous Membranes* in relation with the Diaphragm are four in number: three lining its upper or thoracic surface; one, its abdominal. The three serous membranes on its upper surface are the pleura on either side and the serous layer of the pericardium, which covers the middle portion of the tendinous centre. The serous membrane covering its under surface is a portion of the general peritoneal membrane of the abdominal cavity.

The Diaphragm is arched, being convex toward the chest and concave to the abdomen. The *right portion* forms a complete arch from before backward, being accurately moulded over the convex surface of the liver, and having resting upon it the concave base of the right lung. The *left portion* is arched from before backward in a similar manner; but the arch is narrower in front, being encroached upon by the pericardium, and lower than the right, at its summit, by about three-quarters of an inch. It supports the base of the left lung, and covers the great end of the stomach, the spleen, and left kidney. At its circumference the Diaphragm is higher in the mesial line of the body than at either side; but in the middle of the thorax the central portion, which supports the heart, is on a lower level than the two lateral portions.

**Nerves.**—The Diaphragm is supplied by the phrenic nerves and phrenic plexus of the sympathetic.

**Actions.**—The Diaphragm is the principal muscle of inspiration. When in a condition of rest the muscle presents a domed surface, concave toward the abdomen; and consists of a circumferential muscular and a central tendinous part. When the muscular fibres contract, they become less arched, or nearly straight, and thus cause the central tendon to descend, and in consequence the level of the chest-wall is lowered, the vertical diameter of the chest being proportionally increased. In this descent the different parts of the tendon move unequally. The left leaflet descends to the greatest extent; the right to a less extent, on
account of the liver; and the central leaflet the least, because of its connection to the pericardium. In descending the diaphragm presses on the abdominal viscera, and so to a certain extent causes a projection of the abdominal wall; but in consequence of these viscera not yielding completely, the central tendon becomes a fixed point, and enables the circumferential muscular fibres to act from it, and so elevate the lower ribs and expand the lower part of the thoracic cavity; and Duchenne has shown that the Diaphragm has the power of elevating the ribs, to which it is attached, by its contraction, if the abdominal viscera are in situ, but that if these organs are removed, this power is lost. When at the end of inspiration the Diaphragm relaxes, the thoracic walls return to their natural position in consequence of their elastic reaction and of the elasticity and weight of the displaced viscera.1

In all expulsive acts the Diaphragm is called into action, to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, and crying, before vomiting, previous to the expulsion of the urine and feces, or of the fetus from the womb, a deep inspiration takes place.

The height of the Diaphragm is constantly varying during respiration, the muscle being carried upward or downward from the average level; its height also varies according to the degree of distension of the stomach and intestines, and the size of the liver. After a forced expiration, the right arch is on a level, in front, with the fourth costal cartilage; at the side, with the fifth, sixth, and seventh ribs; and behind, with the eighth rib, the left arch being usually from one to two ribs' breadth below the level of the right one. In a forced inspiration, it descends from one to two inches; its slope would then be represented by a line drawn from the ensiform cartilage toward the tenth rib.

**THE ABDOMEN.**

**Superficial Muscles.**

The Muscles in this region are, the

1. Obliquus Externus.
2. Obliquus Internus.
3. Pyramidalis.
4. Transversalis.
5. Rectus.

**Dissection** (Fig. 291).—To dissect the abdominal muscles, make a vertical incision from the ensiform cartilage to the pubes; a second incision from the umbilicus obliquely upward and outward to the outer surface of the chest, as high as the lower border of the fifth or sixth rib; and a third, commencing midway between the umbilicus and pubes, transversely outward to the anterior superior iliac spine, and along the crest of the ilium as far as its posterior third. Then reflect the three flaps included between these incisions from within outward, in the lines of direction of the muscular fibres. If necessary, the abdominal muscles may be made tense by inflating the peritoneal cavity through the umbilicus.

The **Superficial fascia** of the abdomen consists over the greater part of the abdominal wall of a single layer of fascia, which contains a variable amount of fat; but as this layer approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands. The superficial layer is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and outer

---

1 For a detailed description of the general relations of the Diaphragm, and its action, refer to Dr. Shipon's *Medical Anatomy.*
surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its character, becoming thin, destitute of adipose tissue and of a pale reddish color, and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward to be continuous with the superficial fascia of the perineum. In the female this fascia is continued into the labia majora. The deeper layer (fascia of Scarpa) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; and below and internally it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the deep layer of the superficial fascia of the perineum. In the female it is continued into the labia majora.

The External or Descending Oblique muscle (Fig. 292) is situated on the side and fore part of the abdomen; being the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall, of the abdomen. It arises, by eight fleshy digitations, from the external surface and lower borders of the eight inferior ribs; these digitations are arranged in an oblique line running downward and backward; the upper ones being attached close to the cartilages of the corresponding ribs; the lowest, to the apex of the cartilage of the last rib; the intermediate ones, to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downward, and are received between corresponding processes of the Serratus magnus; the three lower ones diminish in size from above downward, receiving between them corresponding processes from the Latissimus dorsi. From these attachments, the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downward, to be inserted into the anterior half of the outer lip of the crest of the ilium; the middle and upper fibres, directed downward and forward, terminate in tendinous fibres, opposite a line drawn from the prominence of the ninth costal cartilage to the anterior superior spinous process of the ilium, which then spread out into a broad aponeurosis.

The Aponeurosis of the External Oblique is a thin, but strong membranous aponeurosis, the fibres of which are directed obliquely downward and inward. It is joined with that of the opposite muscle along the median line, covers the whole of the front of the abdomen; above, it is connected with the lower border of the Pectoralis major; below, its fibres are closely aggregated together, and extend obliquely across from the anterior superior spine of the ilium to the spine of the os pubis and the linea ilipectinea. In the median line it interlaces with the aponeurosis of the opposite muscle, forming the linea alba, which extends from the ensiform cartilage to the symphysis pubis. That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward, and continuous below with the fascia lata; it is called Poupart's ligament. The portion which is reflected from Poupart's ligament at the spine of the os pubis along the pectineal line is called Gimbert's ligament. From the point of attachment of the latter to the pectineal line, a few fibres pass upward and inward, behind the inner pillar of the ring, to the linea alba. They diverge as they ascend, and form a thin, triangular, fibrous band, which is called the triangular ligament of the abdomen.

In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the external abdominal ring, formed by a separation of the fibres of the aponeurosis in this situation.

Relations.—By its external surface, with the superficial fascia, superficial epigastric and circumflex iliae vessels, and some cutaneous nerves; by its internal surface, with the Internal oblique, the lower part of the eight inferior ribs, and
OF THE ABDOMEN.

Intercostal muscles, the Cremaster, the spermatic cord in the male, and round ligament in the female. Its posterior border, extending from the last rib to the crest of the ilium, is fleshy throughout and free; it is occasionally overlapped by the Latissimus dorsi, though generally a triangular interval exists between the two muscles near the crest of the ilium, in which is seen a portion of the internal oblique. This triangle, Petit's triangle, is therefore bounded in front by the

External oblique, behind by the Latissimus dorsi, below by the crest of the ilium, while its floor is formed by the Internal oblique (Fig. 287).

The following parts of the aponeurosis of the External oblique muscle require to be further described: viz. the external abdominal ring, the intercolumnar fibres and fascia, Poupart's ligament, Gimbernat's ligament, and the triangular ligament of the abdomen.

The External Abdominal Ring.—Just above, and to the outer side of the crest of the os pubis, an interval is seen in the aponeurosis of the External oblique, called the External abdominal ring. The aperture is oblique in direction, some-
what triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the intercolumnar, which pass across the upper angle of the ring, so as to increase its strength; and on each side, by the margins of the opening in the aponeurosis, which are called the columns or pillars of the ring.

The external pillar, which is at the same time inferior from the obliquity of its direction, is the stronger: it is formed by that portion of Poupart’s ligament which is inserted into the spine of the os pubis; it is curved so as to form a kind of groove, upon which the spermatic cord rests. The internal or superior pillar is a broad, thin, flat band which is attached to the front of the symphysis pubis, interlacing with its fellow of the opposite side, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male, and round ligament in the female: it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the greater frequency of inguinal hernia in men.

The intercolumnar fibres are a series of curved tendinous fibres, which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring, describing a curve with the convexity downward. They are much thicker and stronger at the outer margin of the external ring, where they are connected to the outer third of Poupart’s ligament, than internally, where they are inserted into the linea alba. They are more strongly developed in the male than in the female. The intercolumnar fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from one another.

These intercolumnar fibres as they pass across the external abdominal ring are themselves connected together by delicate fibrous tissue, thus forming a fascia, which, as it is attached to the pillars of the ring covers it in, and is called the intercolumnar fascia. This intercolumnar fascia is continued down as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence it is also called the external spermatic fascia.

The sac of an inguinal hernia, in passing through the external abdominal ring, receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external abdominal ring and the limb is then extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense, and the external ring much contracted; if the limb is on the contrary flexed upon the pelvis and rotated inward, this aponeurosis will become lax and the external abdominal ring sufficiently enlarged to admit the finger with comparative ease: hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia in order that the abdominal walls may be relaxed as much as possible.

Poupart’s ligament, or the crural arch, is the lower border of the aponeurosis of the External oblique muscle, and extends from the anterior superior spine of the ilium to the pubic spine. From this latter point it is reflected outward to be attached to the pectineal line for about half an inch, forming Gimbernat’s ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

Nearly the whole of the space included between the crural arch and the innominate bone is filled in by the parts which descend from the abdomen into the thigh. These will be referred to again on a subsequent page.

Gimbernat’s ligament is that part of the aponeurosis of the External oblique
muscle which is reflected downward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form with the base directed outward. Its base, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath. Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

The triangular ligament of the abdomen is a band of tendinous fibres of a triangular shape, which is attached by its apex to the pectineal line, where it is continuous with Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring, and in front of the conjointed tendon, and interlaces with the ligament of the other side at the linea alba.

Dissection.—Detach the External oblique by dividing it across, just in front of its attachment to the ribs, as far as its posterior border, and separate it below from the crest of the ilium as far as the anterior superior spine; then separate the muscle carefully from the Internal oblique, which lies beneath, and turn it toward the opposite side.

The Internal or Ascending oblique muscle (Fig. 293), thinner and smaller than the preceding, beneath which it lies, is of an irregularly quadrilateral form,
upper surface; from the anterior two-thirds of the middle lip of the crest of the ilium, and from the posterior lamella of the lumbar fascia. From this origin, the fibres diverge: those from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, to the extent of half an inch, forming what is known as the conjoined tendon of the Internal oblique and Transversalis; those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus muscle to be inserted into the linea alba; those which arise from the middle third of the origin from the crest of the ilium pass obliquely upward and inward, and terminate in an aponeurosis, which divides opposite the linea semilunaris into two lamellae, which are continued forward, in front and behind the Rectus muscle, to the linea alba, the posterior lamella being also connected to the cartilages of the seventh, eighth, and ninth ribs; the most posterior fibres pass almost vertically upward, to be inserted into the lower borders of the cartilages of the three lower ribs, being continuous with the Internal intercostal muscles.

The conjoined tendon of the Internal oblique and Transversalis is inserted into the crest of the os pubis and pectineal line, immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia; or the hernia forces its way through the fibres of the conjoined tendon.

The aponeurosis of the Internal oblique is continued forward to the middle line of the abdomen, where it joins with the aponeurosis of the opposite muscle at the linea alba, and extends from the margin of the thorax to the os pubis. At the outer margin of the Rectus muscle, this aponeurosis, for the upper three-fourths of its extent, divides into two lamellae, which pass, one in front and the other behind the muscle, enclosing it in a kind of sheath, and reuniting on its inner border at the linea alba; the anterior layer is blended with the aponeurosis of the External oblique muscle; the posterior layer with that of the Transversalis. Along the lower fourth the aponeurosis passes altogether in front of the Rectus without any separation.

Relations.—By its external surface, with the External oblique, Latissimus dorsi, spermatic cord, and external ring; by its internal surface, with the Transversalis muscle, the lower intercostal vessels and nerves, the ilio-hypogastric and the ilio-inguinal nerves. Near Poupart's ligament it lies on the fascia transversalis, internal ring, and spermatic cord. Its lower border forms the upper boundary of the spermatic canal.

The Cremaster muscle is a thin muscular layer, composed of a number of fasciculi which arise from the middle of Poupart's ligament at the inner side of the Internal oblique, being connected with that muscle, and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external abdominal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the fascia cremasterica. The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of foetal life the testis is placed at the lower and back
part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched fibres of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part which accompany the testicle and cord into the scrotum. It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis, in its descent, passed through instead of beneath the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal hernia. No such muscles exist in the female, but an analogous structure is developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

Dissection.—Detach the Internal oblique in order to expose the Transversalis beneath. This may be effected by dividing the muscle, above, at its attachment to the ribs; below, at its connection with Poupart's ligament and the crest of the ilium; and behind, by a vertical incision extending from the last rib to the crest of the ilium. The muscle should previously be made tense by drawing upon it with the fingers of the left hand, and if its division is carefully effected, the cellular interval between it and the Transversalis, as well as the direction of the fibres of the latter muscle, will afford a clear guide to their separation; along the crest of the ilium the circumflex iliac vessels are interposed between them, and form an important guide in separating them. The muscle should then be thrown forward toward the linea alba.

The Transversalis muscle (Fig. 294), so called from the direction of its fibres, is the most internal flat muscle of the abdomen, being placed immediately beneath the Internal oblique. It arises by fleshy fibres from the outer third of Poupart's ligament; from the inner lip of the crest of the ilium for its anterior three-fourths; from the inner surface of the cartilages of the six lower ribs, interdigitating with the Diaphragm; and by the middle layer of the lumbar fascia (posterior aponeurosis of the muscle itself) from the tips of the transverse processes of the lumbar vertebrae. The muscle terminates in front in a broad aponeurosis, the lower fibres of which curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. Throughout the rest of its extent the aponeurosis passes horizontally inward, and is inserted into the linea alba; its upper three-fourths passing behind the Rectus muscle, blending with the posterior lamella of the Internal oblique; its lower fourth passing in front of the Rectus.

Relations.—By its external surface, with the Internal oblique, and the inner surface of the cartilages of the lower ribs; by its internal surface, with the fascia transversalis, which separates it from the peritoneum. Its lower border forms the upper boundary of the spermatic canal.

Dissection.—To expose the Rectus muscle, open its sheath by a vertical incision extending from the margin of the thorax to the os pubis, and then reflect the two portions from the surface of the muscle, which is easily done, excepting at the linea transverse, where so close an adhesion exists that the greatest care is requisite in separating them. Now raise the outer edge of the muscle, in order to examine the posterior layer of the sheath. By dividing the muscle in the centre, and turning its lower part downward, the point where the posterior wall of the sheath terminates in a thin curved margin will be seen.

The Rectus abdominis is a long flat muscle, which extends along the whole length of the front of the abdomen, being separated from its fellow of the opposite side by the linea alba. It is much broader, but thinner, above than below, and arises by two tendons, the external or larger being attached to the crest of the os pubis, the internal, smaller portion interlacing with its fellow of the opposite side, and being connected with the ligaments covering the front of the symphysis pubis. The fibres ascend, and the muscle is inserted by three portions of unequal size into the cartilages of the fifth, sixth, and seventh ribs. Some fibres are occasionally connected with the costo-xiphoïd ligaments and side of the ensiform cartilage.

The Rectus muscle is traversed by tendinous intersections, three in number.
which have received the name of _lineae transversae_. One of these is usually situated opposite the umbilicus, and two above that point; of the latter, one corresponds to the extremity of the ensiform cartilage, and the other to the interval between the ensiform cartilage and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance, sometimes pass only halfway across it, and are intimately adherent in front to the sheath in which the muscle is enclosed.

The Rectus is enclosed in a sheath (Fig. 295) formed by the aponeuroses of the Oblique and Transversalis muscles, which are arranged in the following manner. When the aponeurosis of the Internal oblique arrives at the outer margin of the Rectus, it divides into two lamellae, one of which passes in front of the Rectus, blending with the aponeurosis of the External oblique; the other, behind it, blending with the aponeurosis of the Transversalis; and these, joining again at its
inner border, are inserted into the linea alba. This arrangement of the aponeuroses exists along the upper three-fourths of the muscle; at the commencement of the lower fourth, the posterior wall of the sheath terminates in a thin curved margin, the semilunar fold of Douglas, the concavity of which looks downward toward the pubes; the aponeuroses of all three muscles passing in front of the Rectus without any separation. The extremities of the fold of Douglas descend as pillars to the os pubis. The inner pillar is attached to the symphysis pubis; the outer pillar, which is named by Braune the ligament of Hesselbach, divides below to enclose the internal abdominal ring; the internal fibres are attached to the horizontal ramus of the os pubis and the pectineal fascia; the external ones pass to the Psoas fascia, and to the Transversalis where it arises from Poupart's ligament on the outer side of the ring. The Rectus muscle, in the situation

where its sheath is deficient, is separated from the peritoneum by the transversalis fascia.

The Pyramidalis is a small muscle, triangular in shape, placed at the lower part of the abdomen, in front of the Rectus, and contained in the same sheath with that muscle. It arises by tendinous fibres from the front of the os pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upward, diminishing in size as it ascends, and terminates by a pointed extremity, which is inserted into the linea alba, midway between the umbilicus and the os pubis. This muscle is sometimes found wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it has been found double on one side, or the muscles of the two sides are of unequal size. Sometimes its length exceeds what is stated above.

Relations.—Its anterior surface is covered by the sheath of the Rectus. Its posterior surface rests against the Rectus itself. To expose the Pyramidalis, make, through the sheath of the Rectus, a vertical incision the lower end of which should begin just a little to one side of, and on a level with, the symphysis pubis.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Internal oblique also receives a filament from the ilio-inguinal nerve. The Cremaster is supplied by the genital branch of the Genito-crural.

In the description of the abdominal muscles mention has frequently been made of the linea alba, linea semilunares, and linea transverse; when the dissection of the muscles is completed these structures should be examined.

The linea alba is a tendinous raphe seen along the middle line of the abdomen, extending from the ensiform cartilage to the symphysis pubis, to which it is
attached. It is placed between the inner borders of the Recti muscles, and is formed by the blending of the aponeuroses of the Obliqui and Transversales muscles. It is narrow below, corresponding to the narrow interval existing between the Recti; but broader above, as these muscles diverge from one another in their ascent, becoming of considerable breadth after great distension of the abdomen from pregnancy or ascites. It presents numerous apertures for the passage of vessels and nerves: the largest of these is the umbilicus, which in the foetus transmits the umbilical vessels, but in the adult is obliterated, the cicatrix being stronger than the neighboring parts; hence umbilical hernia occurs in the adult near the umbilicus, whilst in the foetus it occurs at the umbilicus. The linea alba is in relation, in front, with the integument, to which it is adherent, especially at the umbilicus; behind, it is separated from the peritoneum by the transversalis fascia; and below, by the urachus, and the bladder when that organ is distended.

The lineæ semilunares are two curved tendinous lines placed one on each side of the linea alba. Each corresponds with the outer border of the Rectus muscle, extends from the cartilage of the ninth rib to the pubic spine, and is formed by the aponeurosis of the Internal oblique at its point of division to enclose the Rectus, where it is reinforced in front by the External oblique and behind by the Transversalis.

The lineæ transversæ are three narrow transverse lines which intersect the Recti muscles, as already mentioned; they connect the lineæ semilunares with the linea alba.

Actions.—The abdominal muscles perform a threefold action:

When the pelvis and thorax are fixed, they compress the abdominal viscera, by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the diaphragm. By these means the foetus is expelled from the uterus, the faeces from the rectum, the urine from the bladder, and the contents of the stomach in vomiting.

If the pelvis and spine are fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone is fixed, the thorax is bent directly forward when the muscles of both sides act, or to either side when those of the two sides act alternately, rotation of the trunk at the same time taking place to the opposite side.

If the thorax is fixed, these muscles, acting together, draw the pelvis upward, as in climbing; or, acting singly, they draw the pelvis upward, and rotate the vertebral column to one side or the other. The Recti muscles, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The fascia transversalis is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciae. In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle, but it becomes thin and cellular as it ascends to the diaphragm. Below, it has the following attachments: external to the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the femoral vessels it is thin and attached to the os pubis and pectineal line, behind the conjoined tendon, with which it is united; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the crural sheath. The spermatic cord in the male and the round ligament in the female pass through this fascia: the point where they pass through is called the internal abdominal ring. This opening is not visible externally, owing to a prolongation of the transversalis fascia on the structures, forming the infundibuliform process.

The internal or deep abdominal ring is situated in the transversalis fascia,
midway between the anterior superior spine of the ilium and the spine of the os pubis, and about half an inch above Poupart's ligament. It is of an oval form, the extremities of the oval directed upward and downward, varies in size in different subjects, and is much larger in the male than in the female. It is bounded, above and externally, by the arched fibres of the Transversalis; below and internally, by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin funnel-shaped membrane, the infundibuliform fascia, is continued round the cord and testis, enclosing them in a distinct pouch.

When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

The inguinal or spermatic canal contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal about an inch and a half in length, directed downward and inward, and placed parallel to and a little above Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the spermatic canal, and terminates below at the external ring. It is bounded in front by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; behind, by the triangular ligament, the conjointed tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; above, by the arched fibres of the Internal oblique and Transversalis; below, by the union of the fascia transversalis with Poupart's ligament.

That form of protrusion in which the intestine follows the course of the spermatic cord along the spermatic canal is called oblique inguinal hernia.

The Deep Crural Arch.—Passing across the front of the crural arch, on the abdominal side of Poupart's ligament and closely connected with it, is a thickened band of fibres called the deep crural arch. It is apparently a thickening of the fascia transversalis, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath to be inserted by a broad attachment into the pectineal line, behind the conjointed tendons. In some subjects this structure is not very prominently marked, and not unfrequently it is altogether wanting.

Surface Form.—The only two muscles of this group which have any considerable influence on surface form are the External oblique and Rectus muscles of the abdomen. With regard to the External oblique, the upper digitations of its origin from the ribs are well marked, intermingled with the serrations of the Serratus magnus; the lower digitations are not visible, being covered by the thick border of the Latissimus dorsi. Its attachment to the crest of the ilium, in conjunction with the Internal oblique, forms a thick oblique roll, which determines the iliac furrow. Sometimes on the front of the lateral region of the abdomen an undulating outline marks the spot where the muscular fibres terminate and the aponeurosis commences. The outer border of the Rectus is defined by the linea semilunaris, which may be exactly defined by putting the muscle into action. It corresponds with a curved line, with its convexity outward, drawn from the lowest part of the cartilage of the seventh rib to the spine of the os pubis, so that the centre of the line, at or near the umbilicus, is three inches from the median line. The inner border of the Rectus corresponds to the linea alba, marked on the surface of the body by a groove, the abdominal furrow, which extends from the infrasternal fossa to, or to a little below, the umbilicus, where it gradually becomes lost. The surface of the Rectus presents three transverse furrows, the linea transversa, the upper two of these, one opposite or a little below the tip of the ensiform cartilage, and another, midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. The umbilicus, situated in the linea alba, varies very much in position as regards its height. It is always situated above a zone drawn round the body opposite the highest point of the crest of the ilium, generally being about three-quarters of an inch to an inch above this line. It generally corresponds, therefore, to the fibro-cartilage between the third and fourth lumbar vertebrae.

Deep Muscles of the Abdomen.

Psoas parvus. Iliacus.
Psoas magnus. Quadratus lumborum.
The Psoas magnus, the Psoas parvus, and the Iliacus muscles, with the fascia covering them, will be described with the Muscles of the Lower Extremity (see page 504).

**The Fascia covering the Quadratus Lumborum.**—This is the most anterior of the two layers of fascia which are given off from the anterior or deep surface of the lumbar fascia (see page 433). It is a thin layer of fascia (part of transversalis fascia), which, passing over the anterior surface of the Quadratus lumborum, is attached, internally, to the anterior surface of the transverse processes of the lumbar vertebrae; below to the ilio-lumbar ligament; and above, to the apex and lower border of the last rib.

The portion of this fascia which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib constitutes the ligamentum arcuatum externum.

**The Quadratus lumborum** (Fig. 288, page 435) is situated in the lumbar region. It is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the ilio-lumbar ligament and the adjacent portion of the crest of the ilium for about two inches, and is inserted into the lower border of the last rib for about half its length and by four small tendons, into the apices of the transverse processes of the four upper lumbar vertebrae. Occasionally a second portion of this muscle is found situated in front of the preceding. This arises from the upper borders of the transverse processes of the lumbar vertebrae, and is inserted into the lower margin of the last rib. The Quadratus lumborum is contained in a sheath formed by the anterior and middle lamelle of the lumbar fascia.

**Relations.**—Its anterior surface (or rather the fascia which covers its anterior surface) is in relation with the colon and the kidney. Its posterior surface is in relation with the middle lamella (posterior aponeurosis of the Transversalis muscle) of the lumbar fascia, which separates it from the Erector spinae. The Quadratus lumborum extends, however, beyond the outer border of the Erector spinae.

**Nerve-supply.**—The anterior branches of the lumbar nerves.

**Actions.**—The Quadratus lumborum draws down the last rib, and acts as a muscle of inspiration; and, at the same time, by fixing the last rib, it opposes the tendency of the Diaphragm to draw it upward, and thus it becomes an assistant to inspiration. If the thorax and spine are fixed, it may act upon the pelvis, raising it toward its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

**Muscles of the Pelvic Outlet or of the Ischio-rectal Region and Perineum.**

- Corrugator cutis ani.
- External sphincter ani.
- Internal sphincter ani.
- Levator ani.
- Coccygeus.
- Transversus perinei.
- Accelerator urethrae.
- Compressor urethrae.

*In Male.*

*In Female.*

- Transversus perinei.
- Sphincter vagine.
- Erector clitoridis.
- Compressor urethrae.

**The Corrugator Cutis Ani.**—Around the anus is a thin stratum of involuntary muscular fibre, which surrounds it in a radiating manner. Internally, the fibres fade off into the submucous tissue, whilst externally they blend with the true skin. By its contraction it raises the skin into ridges radiating from the margin of the anus.

The **External sphincter ani** is a thin, flat plane of muscular fibres, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about three or four inches in length from its anterior to its posterior extremity, being about an inch in breadth opposite the anus. It arises from the tip of the coccyx by a narrow tendinous band, and from the superficial fascia in front of that bone; and is inserted into the central tendinous point of the perineum, joining with the Transversus perinei, the Levator ani, and the Accelerator urinæ. Like other sphincter muscles, it consists of two planes of muscular
fibres, which surround the margin of the anus, and join in a commissure in front and behind.

Nerve-supply.—A branch from the anterior division of the fourth sacral and the inferior hemorrhoidal branch of the internal pudic.

Actions.—The action of this muscle is peculiar: 1. It is, like other muscles, always in a state of tonic contraction, and having no antagonistic muscle it keeps the anal orifice closed. 2. It can be put into a condition of greater contraction under the influence of the will, so as to more firmly occlude the anal aperture. 3. Taking its fixed point at the coccyx, it helps to fix the central point of the perineum, so that the Accelerator may act from this fixed point.

The Internal sphincter is a muscular ring which surrounds the lower extremity of the rectum for about an inch, its inferior border being contiguous, but quite separate from, the External sphincter. This muscle is about two lines in thickness, and is formed by an aggregation of the involuntary circular fibres of the intestine. It is paler in color and less coarse in texture than the External sphincter.

Actions.—Its action is entirely involuntary. It helps the External sphincter to occlude the anal aperture.

The Levator ani (Fig. 296) is a broad, thin muscle, situated on each side of the pelvis. It is attached to the inner surface of the sides of the true pelvis, and descending unites with its fellow of the opposite side to form the floor of the pelvic cavity. It supports the viscera in this cavity and surrounds the various structures which pass through it. It arises, in front, from the posterior surface of the body and ramus of the os pubis on the outer side of the symphysis; posteriorly, from the inner surface of the spine of the ischium; and between these two points from the angle of division between the obturator and recto-vesical layers of the pelvic fascia at their under part. The fibres pass downward to the middle line of the floor of the pelvis, and are inserted, the most posterior into the sides of the apex of the coccyx; those placed more anteriorly unite with the muscles of the opposite side in a median fibrous raphe, which extends between the coccyx and the margin of the anus. The middle fibres, which form the larger portion of the muscle, are
inserted into the side of the rectum, blending with the fibres of the Sphincter muscles; lastly, the anterior fibres, the longest, descend upon the side of the prostate gland to unite beneath it with the muscle of the opposite side, blending with the fibres of the External sphincter and Transversus perinei muscles at the central tendinous point of the perineum.

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate gland, descending by its side, and surrounding it as in a sling, it has been described by Santorini and others as a distinct muscle, under the name of Levator prostate. In the female, the anterior fibres of the Levator ani descend upon the side of the vagina.

Relations.—By its inner or pelvic surface, with the recto-vesical fascia, which separates it from the viscera of the pelvis and from the peritoneum. By its outer or perineal surface, it forms the inner boundary of the ischio-rectal fossa, and is covered by a thin layer of fascia, the ischio-rectal or anal fascia, given off from the obturator fascia. Its posterior border is continuous with the Coccygeus muscle. Its anterior border is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, passes from the pelvis.

Nerve-supply.—A branch from the anterior division of the fourth sacral nerve.

Actions.—This muscle supports the lower end of the rectum and vagina, and also the bladder during the efforts of expulsion. It elevates and inverts the lower end of the rectum after it has been protruded and everted during the expulsion of the faeces. It is also a muscle of forced expiration.

The Coccygeus is situated behind and parallel with the preceding. It is a triangular plane of muscular and tendinous fibres, arising, by its apex, from the spine of the ischium and lesser sacro-sciatic ligament, and inserted, by its base, into the margin of the coccyx and into the side of the lower piece of the sacrum. This muscle is continuous with the posterior border of the Levator ani, and closes in the back part of the outlet of the pelvis.

Relations.—By its inner or pelvic surface, with the rectum; by its external surface, with the lesser sacro-sciatic ligament; by its posterior border, with the Pyriformis.

Nerve-supply.—A branch from the fourth and fifth sacral nerves.

Action.—The Coccygei muscles raise and support the coccyx after it has been pressed backward during defecation or parturition.

Superficial Fascia.—The superficial fascia of the perineum consists of two layers, superficial and deep, as in other regions of the body.

The superficial layer is thick, loose, areolar in texture, and contains much adipose tissue in its meshes, the amount of which varies in different subjects. In front, it is continuous with the dartos of the scrotum; behind, it is continuous with the subcutaneous areolar tissue surrounding the anus; and, on either side, with the same fascia on the inner side of the thighs. This layer should be carefully removed after it has been examined, when the deep layer will be exposed.

The deep layer of superficial fascia (Fascia of Colles) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of the root of the penis. It is continuous, in front, with the dartos of the scrotum; on either side it is firmly attached to the margins of the rami of the os pubis and ischium, external to the crus penis, and as far back as the tuberosity of the ischium; posteriorly, it curves down behind the Transversus perinei muscles to join the lower margin of the deep perineal fascia. This fascia not only covers the muscles in this region, but sends down a vertical septum from its under surface, which separates the back part of the subjacent space into two, being incomplete in front.

The Central Tendinous Point of the Perineum.—This is a fibrous point in the middle line of the perineum, between the urethra and the rectum, being about half an inch in front of the anus. At this point four muscles converge and are attached: viz. the External sphincter ani, the Accelerator urinae, and the two
Transversus perinaei; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The Transversus perinaei is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inward, is inserted into the central tendinous point of the perineum, joining in this situation

with the muscle of the opposite side, the External sphincter ani behind, and the Accelerator urinae in front.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction they serve to fix the central tendinous point of the perineum.

The Accelerator urinae (Ejaculator seminis, or Bulbo-cavernosus) is placed in the middle line of the perineum, immediately in front of the anus. It consists of two symmetrical halves, united along the median line by a tendinous raphe. It arises from the central tendon of the perineum, and from the median raphe in front. From this point its fibres diverge like the plumes of a pen; the most posterior form a thin layer, which are lost on the anterior surface of the triangular ligament; the middle fibres encircle the bulb and adjacent parts of the corpus spongiosum, and join with the fibres of the opposite side, on the upper part of the corpus spongiosum, in a strong aponeurosis; the anterior fibres, the longest and most distinct, spread out over the sides of the corpus cavernosum, to be inserted partly into that body, anterior to the Erector penis, occasionally extending to the os pubis; partly terminating in a tendinous expansion, which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and dissecting it outward from the surface of the urethra.

Action.—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed, by Krause, to assist in the erection of the corpus
spongiosum, by compressing the erectile tissue of the bulb. The anterior fibres, according to Tyrrel, also contribute to the erection of the penis, as they are inserted into, and continuous with, the fascia of the penis, compressing the dorsal vein during the contraction of the muscle.

The Erector penis (Ischio-cavernous) covers part of the crus penis. It is an elongated muscle, broader in the middle than at either extremity, and situated on either side of the lateral boundary of the perineum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis, from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis which is inserted into the sides and under surface of the crus penis.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It compresses the crus penis and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

Between the muscles just examined a triangular space exists, bounded internally by the Accelerator urinæ, externally by the Erector penis, and behind

---

Fig. 298.—The muscles attached to the front of the pelvis. (From a preparation in the Museum of the Royal College of Surgeons of England.)
OF THE PERINEUM.

by the Transversus perinei. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia), and running from behind forward in it are the superficial perineal vessels and nerve, and the transverse perineal artery coursing along the posterior boundary of the space on the Transversus perinei muscle.

The Triangular Ligament (*Deep perineal fascia*) is a dense membranous lamina, which closes the front part of the outlet of the pelvis. It is triangular in shape, about an inch and a half in depth, attached above, by its apex, to the under surface of the symphysis pubis and subpubic ligament; and on each side to the rami of the ischium and pubes, beneath the crura penis. Its inferior margin, or base, is directed toward the rectum, and connected to the central tendinous point of the perineum. It is continuous with the deep layer of the superficial fascia behind the Transversus perinei muscle, and with a thin fascia which covers the cutaneous surface of the Levator ani muscle (anal or ischio-rectal fascia).

The Triangular ligament is perforated by the urethra, about an inch below the symphysis pubis. The aperture is circular in form, and about three or four lines in diameter. Above this is the aperture for the dorsal vein of the penis; and, outside the latter, branches of the pudic nerve and artery pierce it.

The triangular ligament consists of two layers, superficial or inferior, and deep or superior; these are separated in front, but united behind.

The superficial layer on its inferior surface is intimately connected with, and sends an expansion to, the bulb. It is pierced by the duct of Cowper's gland and by the membranous urethra; as is also the following layer.

The deep layer is derived laterally from the obturator fascia; superiorly expansions from it are given off into the sheath of the prostate gland, this sheath, in its turn, being formed from the recto-vesical fascia.

**Structures between the Two Layers of the Triangular Ligament.**—If the superficial layer of this fascia is detached on either side, the following structures

1 "On the Anatomy of the Posterior Layer of the Triangular Ligament," see a paper by Mr Carrington, *Guy's Hospital Reports.*
will be seen between it and the deep layer: the subpubic ligament above, close to the pubes; the dorsal vein of the penis; the membranous portion of the urethra, and the Compressor urethrae muscle; Cowper's glands and their ducts; the pudic vessels and nerve; the artery and nerve of the bulb, and a plexus of veins.

The Compressor urethrae (Constrictor urethrae) surrounds the whole length of the membranous portion of the urethra, and is contained between the two layers of the triangular ligament. It arises, by aponeurotic fibres, from the upper part of the ramus of the os pubis on each side, to the extent of half or three-quarters of an inch; each segment of the muscle passes inward, and divides into two fasciculi, which surround the urethra from the prostate gland behind to the bulbous portion of the urethra in front; and unite, at the upper and lower surfaces of this tube, with the muscle of the opposite side, by means of a tendinous raphe.

**Actions.**—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the Acceleratores urinae, are relaxed, and only come into action at the end of the process to eject the last of the fluid.

**Muscles of the Perineum in the Female.**

The Transversus perinei in the female is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inward, is inserted into the central line of the perineum, joining in this situation with the muscle of the opposite side, the External sphincter ani behind, and the Sphincter vaginae in front.

**Nerve-supply.**—The perineal branch of the internal pudic.

**Actions.**—By their contraction they serve to fix the central tendinous point of the perineum.

The Sphincter vaginae surrounds the orifice of the vagina, and is analogous to the Accelerator urinæ in the male. It is attached posteriorly to the central
tendinous point of the perineum, where it blends with the External sphincter ani. Its fibres pass forward on each side of the vagina, to be inserted into the corpora cavernosa of the clitoris, a fasciculus crossing over the body of the organ so as to compress the dorsal vein.

**Nerve-supply.**—The perineal branch of the internal pudic.

**Actions.**—It diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris; compressing the dorsal vein during the contraction of the muscle.

The *Erector clitoridis* resembles the Erector penis in the male, but is smaller than it. It covers the unattached part of the crus clitoridis. It is an elongated muscle, broader at the middle than at either extremity, and situated on either side of the lateral boundary of the perineum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis, which is inserted into the sides and under surface of the crus clitoridis.

**Nerve-supply.**—The perineal branch of the internal pudic.

**Actions.**—It compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The *triangular ligament* (*deep perineal fascia*) in the female is not so strong as in the male. It is attached to the pubic arch, its apex being connected with the symphysis pubis. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended, and in front of this is perforated by the urethra. Its posterior border is continuous, as in the male, with the deep layer of the superficial fascia around the Transversus perinei muscle.

**Structures between the Two Layers of the Triangular Ligament.**—The subpubic ligament above, the dorsal vein of the clitoris, the urethra and the Compressor urethrae muscle, the glands of Bartholin and their ducts; the pudic vessels and the dorsal nerve of the clitoris; the artery of the bulb of the vestibule, and a plexus of veins.

The *Compressor urethrae* (*constrictor urethrae or deep transversus perinei*) arises on each side from the margin of the descending ramus of the os pubis. The fibres, passing inward, divide into two sets; those of the fore part of the muscle are directed across the subpubic arch in front of the urethra to blend with the muscular fibres of the opposite side; while those of the hinder and larger part pass inward to blend with the wall of the vagina behind the urethra.

**MUSCLES AND FASCIAE OF THE UPPER EXTREMITY.**

The Muscles of the Upper Extremity are divisible into groups, corresponding with the different regions of the limb.

**OF THE SHOULDER.**

*Anterior Thoracic Region.*

THE MUSCLES AND FASCIAE.

Deep Layer:
- Flexor profundus digitorum.
- Flexor longus pollicis.
- Pronator quadratus.

Radial Region.
- Supinator longus.
- Extensor carpi radialis longior.
- Extensor carpi radialis brevior.

Posterior Radio-ulnar Region.
- Extensor communis digitorum.
- Extensor minimi digitii.
- Extensor carpi ulnaris.
- Anconeus.
- Supinator brevis.
- Extensor ossis metacarpi pollicis.
- Extensor brevis pollicis.
- Extensor longus pollicis.
- Extensor indicis.

Dissection of Pectoral Region and Axilla (Fig. 301).—The arm being drawn away from the side nearly at right angles with the trunk, and rotated outward, make a vertical incision through the integument in the median line of the chest, from the upper to the lower part of the sternum; a second incision along the lower border of the Pectoral muscle, from the ensiform cartilage to the inner side of the axilla; a third, from the sternum along the clavicle, as far as its centre; and a fourth, from the middle of the clavicle obliquely downward, along the interspace between the Pectoral and Del-toid muscles, as low as the fold of the armpit. The flap of integument is then to be dissected off in the direction indicated in the figure, but not entirely removed, as it should be replaced on completing the dissection. If a transverse incision is now made from the lower end of the sternum to the side of the chest, as far as the posterior fold of the armpit, and the integument reflected outward, the axillary space will be more completely exposed.

Fasciæ of the Thorax.

The superficial fascia of the thoracic region is a loose cellulo-fibrous layer enclosing masses of fat in its spaces. It is continuous with the superficial fascia of the neck and upper extremity above, and of the abdomen below. Opposite the mamma, it divides into two layers, one of which passes in front, the other behind that gland; and from both of these layers numerous septa pass into its substance, supporting its various lobes: from the anterior layer fibrous processes pass forward to the integument and nipple. These processes were called by Sir A. Cooper the ligamenta suspensoria, from the support they afford to the gland in this situation.

The deep fascia of the thoracic region is a thin aponeurotic lamina, covering the surface of the great Pectoral muscle, and sending numerous prolongations...
between its fasciculi: it is attached, in the middle line, to the front of the sternum; and, above, to the clavicle. It is very thin over the upper part of the muscle, thicker in the interval between the Pectoralis major and Latissimus dorsi, where it closes in the axillary space, and divides at the outer margin of the latter muscle into two layers, one of which passes in front, and the other behind it; these proceed as far as the spinous processes of the dorsal vertebrae, to which they are attached. At the lower part of the thoracic region this fascia is well developed, and is continuous with the fibrous sheath of the Recti muscles.

THE SHOULDER.

Anterior Thoracic Region.

Pectoralis major.  Pectoralis minor.

Subclavius.

The Pectoralis major (Fig. 302) is a broad, thick, triangular muscle, situated at the upper and fore part of the chest, in front of the axilla. It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; this portion of its origin consists of aponeurotic fibres, which intersect with those of the opposite muscle; it also arises from the cartilages of all the true ribs, with the exception, frequently, of the first or of the seventh, or both; and from the aponeurosis of the External oblique muscle of the abdomen. The fibres from this extensive origin converge toward its insertion, giving to the muscle a radiated appearance. Those fibres which arise from the clavicle pass obliquely outward and downward, and are usually separated from the rest by a cellular interval: those from the lower part of the sternum, and the cartilages of the lower true ribs, pass upward and outward, whilst the middle fibres pass horizontally. They all terminate in a flat tendon, about two inches broad, which is inserted into the anterior, bicipital ridge of the humerus. This tendon consists of two laminae, placed one in front of the other, and usually blended together below. The anterior, the thicker, receives the clavicular and upper half of the sternal portion of the muscle; and its fibres are inserted in the same order as that in which they arise; that is to say, the outermost fibres of origin from the clavicle are inserted at the uppermost part of the tendon; the upper fibres of origin from the sternum pass down to the lowermost part of this anterior lamina of the tendon and extend as low as the tendon of the Deltoid and join with it. The posterior lamina of the tendon receives the attachment of the lower half of the sternal portion and the deeper part of the muscle from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, ascend the higher, turning backward successively behind the superficial and upper ones, so that the tendon appears to be twisted. The posterior lamina reaches higher on the humerus than the anterior one, and from it an expansion is given off which covers the bicipital groove and blends with the capsule of the shoulder-joint. Another expansion passes downward to the fascia of the arm.

Relations.—By its anterior surface, with the integument, the superficial fascia, the Platysma, the mammary gland, and the deep fascia; by its posterior surface: its thoracic portion, with the sternum, the ribs and costal cartilages, the costo-coracoid membrane, the Subclavius, Pectoralis minor, Serratus magnus, and the Intercostals; its axillary portion forms the anterior wall of the axillary space, and covers the axillary vessels and nerves, the Biceps and Coraco-brachialis muscles. Its upper border lies parallel with the Deltoid, from which it is separated by a slight interspace in which lie the cephalic vein and descending branch of the acromial thoracic artery. Its lower border forms the anterior margin of the axilla, being at first separated from the Latissimus dorsi by a considerable interval; but both muscles gradually converge toward the outer part of the space.

Dissection.—Detach the Pectoralis major by dividing the muscle along its attachment to the clavicle, and by making a vertical incision through its substance a little external to its line of
attachment to the sternum and costal cartilages. The muscle should then be reflected outward, and its tendon carefully examined. The Pectoralis minor is now exposed, and immediately above it, in the interval between its upper border and the clavicle, a strong fascia, the costo-coracoid membrane.

The **costo-coracoid membrane** is a strong fascia placed between the clavicle and the upper border of the Pectoralis minor muscle, which protects the axillary vessels and nerves. Above, it is attached to the anterior margin of the Subclavian groove on the under surface of the clavicle, and is connected with a layer of cervical fascia which overlies the Omo-hyoid muscle, and forms the posterior layer of the sheath of the Subclavius muscle. Internally, it is attached to the first rib internal to the origin of the Subclavius muscle. Externally it is very thick and dense, and is attached to the coracoid process. The portion extending from its attachment to the first rib to the coracoid process is often whiter and denser than the rest; this is sometimes called the **costo-coracoid ligament**. Below, it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest the muscle; from the lower border of the Pectoralis minor it is continued down-
ward to join the axillary fascia, and outward to join the fascia over the short head of the Biceps. The costo-coracoid membrane is pierced by the cephalic vein, the acromial thoracic artery and vein, superior thoracic artery, and anterior thoracic nerves.

The **Pectoralis minor** (Fig. 303) is a thin, flat, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It arises by three tendinous digitations from the upper margin and outer surface of the third, fourth, and fifth ribs, near their cartilages, and from the aponeurosis covering the Intercostal muscles; the fibres pass upward and outward, and converge to form a flat tendon, which is inserted into the inner border and upper surface of the coracoid process of the scapula.

**Relations.**—By its anterior surface, with the Pectoralis major and the superior thoracic vessels and nerves; by its posterior surface, with the ribs, Intercostal muscles, Serratus magnus, the axillary space, and the axillary vessels and nerves. Its upper border is separated from the clavicle by a triangular interval, broad internally, narrow externally, bounded in front by the costo-coracoid membrane, and internally by the ribs. In this space are the first part of the axillary vessels and nerves.

The costo-coracoid membrane should now be removed, when the Subclavius muscle will be seen.

The **Subclavius** is a long, thin, spindle-shaped muscle, placed in the interval between the clavicle and the first rib. It arises by a short, thick tendon from the first rib and its cartilage at their junction, in front of the rhomboid ligament; the
fleshy fibres proceed obliquely upward and outward, to be inserted into a deep groove on the under surface of the middle third of the clavicle.

**Relations.**—By its upper surface, with the clavicle. By its under surface it is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its anterior surface is separated from the Pectoralis major by the costo-coracoid membrane, which, with the clavicle, forms an osseo-fibrous sheath in which the muscle is enclosed.

If the costal attachment of the Pectoralis minor is divided across, and the muscle reflected outward, the axillary vessels and nerves are brought fully into view, and should be examined.

**Nerves.**—The Pectoral muscles are supplied by the anterior thoracic nerves; the Subclavius, by a filament from the cord formed by the union of the fifth and sixth cervical nerves.

**Actions.**—If the arm has been raised by the Deltoid, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forward the arm, bringing it across the front of the chest, and at the same time rotates it inward. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downward and inward to the thorax, and throwing the inferior angle backward. The Subclavius depresses the shoulder, drawing the clavicle downward and forward. When the arms are fixed, all three muscles act upon the ribs, drawing them upward and expanding the chest, and thus becoming very important agents in forced inspiration. Asthmatic patients always assume an attitude which fixes the shoulders, so that all these muscles may be brought into action to assist in dilating the cavity of the chest.

**Lateral Thoracic Region.**

**Serratus magnus.**

The *Serratus magnus* (Fig. 304) is a broad, thin, and irregularly quadrilateral muscle, situated at the upper part and side of the chest. It consists of two triangular or fan-shaped portions; the upper one having the apex of the triangle attached to the first and second ribs, and the base to the upper angle and vertebral border of the scapula; the lower with its apex behind attached to the inferior angle of the scapula, and its base in front connected with the ribs from the second to the eighth. It arises by nine fleshy digitations from the outer surface and upper border of the eight upper ribs (the second rib having two), and from the aponeurosis covering the upper intercostal muscles, and is inserted into the whole length of the anterior aspect of the posterior border of the scapula. The upper fan-shaped portion is attached to the fore part of the outer surfaces of the first and second ribs; its fibres spread out, the upper ones forming a thick fasciculus, which passes upward and backward, and is attached to the triangular smooth surface on the anterior aspect of the superior angle of the scapula; the remaining fibres proceed backward and downward to
be attached to the posterior border of the scapula between the superior and inferior angles. The lower fan-shaped portion is attached posteriorly by its apex to the anterior surface of the inferior angle of the scapula, partly by muscular, partly by tendinous fibres; it spreads out like a fan, the upper fibres passing forward and upward, the lower horizontally forward to be inserted into the outer surface of the fore part of the ribs from the second to the eighth, by a series of muscular digitations. In the intervals between the four lower of these are received corresponding processes of the External oblique.

Relations.—This muscle is covered, in front, by the Pectoral muscle; behind by the Subscapularis; above, by the axillary vessels and nerves. Its deep surface rests upon the ribs and Intercostal muscles.

Nerves.—The Serratus magnus is supplied by the posterior thoracic nerve.

Actions.—The Serratus magnus, as a whole, carries the scapula forward, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forward the lower angle and assist the Trapezius in rotating the bone round an axis through its centre, and thus assists this muscle in raising the acromion and supporting weights upon the shoulder. It is possible that when the shoulders are fixed the lower fibres may assist in raising and evertting the ribs; but it is not the important inspiratory muscle which it was formerly believed to be.

Surgical Anatomy.—When the muscle is paralyzed the vertebral border, and especially the lower angle, leave the ribs and stand out prominently on the surface, giving a peculiar "winged" appearance to the back. The patient is unable to raise the arm above a right angle, and an attempt to do so is followed by a revolution of the scapula, instead of by the elevation of the arm.

Dissection.—After completing the dissection of the axilla, if the muscles of the back have been dissected, the upper extremity should be separated from the trunk. Saw through the clavicle at its centre, and then cut through the muscles which connect the scapula and arm with the trunk, viz.: the Pectoralis minor in front, Serratus magnus at the side, and the Levator anguli scapulae, the Rhomboids, Trapezius, and Latissimus dorsi behind. These muscles should be cleaned and traced to their respective insertions. Then make an incision through the integument, commencing at the outer third of the clavicle, and extending along the margin of that bone, the acromion process, and spine of the scapula; the integument should be dissected from above downward and outward, when the fascia covering the Deltoid is exposed (Fig. 301, No. 3).

The superficial fascia of the upper extremity is a thin cellulo-fibrous layer, containing the superficial veins and lymphatics, and the cutaneous nerves. It is most distinct in front of the elbow, and contains very large superficial veins and nerves; in the hand it is hardly demonstrable, the integument being closely adherent to the deep fascia by dense fibrous bands. Small subcutaneous bursae are found in this fascia over the acromion, the olecranon, and the knuckles. The deep fascia of the upper extremity comprises the aponeurosis of the shoulder, arm, and forearm, the anterior and posterior annular ligaments of the carpus, and the palmar fascia. These will be considered in the description of the muscles of the several regions.

Acromial Region.

Deltoid.

The deep fascia covering the Deltoid (deltoid aponeurosis) is a fibrous layer which covers the outer surface of the muscle, thick and strong behind, where it is continuous with the infraspinatus fascia, thinner over the rest of its extent. It sends down numerous prolongations between the fasciculi of the muscle. In front, it is continuous with the fascia covering the great Pectoral muscle; behind, with that covering the Infraspinatus; above, it is attached to the clavicle, the acromion, and spine of the scapula; below, it is continuous with the deep fascia of the arm.

The Deltoid (Fig. 302) is a large, thick, triangular muscle, which gives the rounded outline to the shoulder, and has received its name from its resemblance to the Greek letter Α reversed. It surrounds the shoulder-joint in the greater part of its extent, covering it on its outer side, and in front and behind. It arises from
the outer third of the anterior border and upper surface of the clavicle; from the outer margin and upper surface of the acromion process, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its inner end. From this extensive origin the fibres converge toward their insertion, the middle passing vertically, the anterior obliquely backward, the posterior obliquely forward; they unite to form a thick tendon, which is inserted into a rough prominence on the middle of the outer side of the shaft of the humerus. At its insertion the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its muscular fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion process—consists of oblique fibres, which arise in a bipenniform manner from the sides of tendinous intersections, generally four in number, which are attached above to the acromion process and pass downward parallel to one another in the substance of the muscle. The oblique muscular fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upward from the insertion of the muscle into the humerus and alternate with the descending septa. The lateral portions of the muscle—that is to say, the fibres arising from the clavicle and spine of the scapula—are not arranged in this manner, but consist of parallel fasciculi passing from their origin above, to be inserted into the margins of the inferior tendon.

Relations.—By its superficial surface, with the integument, the superficial fascia, Platysma, and supra-acromial nerves. Its deep surface is separated from the head of the humerus by a large sacculated synovial bursa, and covers the coracoacromial process, coracoacromial ligament, Pectoralis minor, Coraco-brachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the scapular and external heads of the Triceps, the circumflex vessels and nerve, and the humerus. Its anterior border is separated at its upper part from the Pectoralis major by a cellular interspace, which lodges the cephalic vein and descending branch of the acromial thoracic artery; lower down the two muscles are in close contact. Its posterior border rests on the Infraspinatus and Triceps muscles.

Nerves.—The Deltoide is supplied by the circumflex nerve.

Actions.—The Deltoide raises the arm directly from the side, so as to bring it at right angles with the trunk. Its anterior fibres, assisted by the Pectoralis major, draw the arm forward; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backward.

Surgical Anatomy.—The Deltoide is very liable to atrophy, and when in this condition simulates dislocation of the shoulder-joint, as there is flattening of the shoulder and apparent prominence of the acromion process; upon examination, however, it will be found that the relative position of the great tuberosity of the humerus to the acromion and coracoacromial process is unchanged. Atrophy of the Deltoide may be due to disuse or loss of trophic influence, either from injury to the circumflex nerve or cord lesions, as in infantile paralysis.

Dissection.—Divide the Deltoide across, near its upper part, by an incision carried along the margin of the clavicle, the acromion process, and spine of the scapula, and reflect it downward: the bursa will be seen on its under surface, as well as the circumflex vessels and nerve.

Anterior Scapular Region.

Subscapularis.

The subscapular fascia is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its inner surface to some of the fibres of the Subscapularis muscle: when this is removed, the Subscapularis muscle is exposed.

The Subscapularis (Fig. 303) is a large triangular muscle which fills up the subscapular fossa, arising from its internal two-thirds, with the exception of a narrow margin along the posterior border, and the surfaces at the superior and inferior angles which afford attachment to the Serratus magnus. Some fibres
arise from tendinous laminae, which intersect the muscle, and are attached to ridges on the bone; and others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps. The fibres pass outward, and gradually converging, terminate in a tendon, which is inserted into the lesser tuberosity of the humerus. Those fibres which arise from the axillary border of the scapula are inserted into the neck of the humerus to the extent of an inch below the tuberosity. The tendon of the muscle is in close contact with the capsular ligament of the shoulder-joint, and glides over a large bursa, which separates it from the base of the coracoid process. This bursa communicates with the cavity of the joint by an aperture in the capsular ligament.

**Relations.**—By its anterior surface, with the Serratus magnus, Coracobrachialis, and Biceps, the axillary vessels and nerves, and the subscapular vessels and nerves; by its posterior surface, with the scapula and the capsular ligament of the shoulder-joint. Its lower border is contiguous with the Teres major and Latissimus dorsi.

**Nerves.**—It is supplied by the upper and lower subscapular nerves.

**Actions.**—The Subscapularis rotates the head of the humerus inward; when the arm is raised, it draws the humerus downward. Together with the following muscles it is a defence to the shoulder-joint, as, by their tension, they all prevent displacement of the head of the bone.

**Posterior Scapular Region** (Fig. 305).

</table>

**Dissection.**—To expose these muscles, and to examine their mode of insertion into the humerus, detach the Deltoid and Trapezius from their attachment to the spine of the scapula and acromion process. Remove the clavicle by dividing the ligaments connecting it with the coracoid process, and separate it at its articulation with the scapula: divide the acromion process near its root with a saw. The fragments being removed, the tendons of the posterior Scapular muscles will be fully exposed, and can be examined. A block should be placed beneath the shoulder-joint, so as to make the muscles tense.

The **Supraspinous fascia** is a thick and dense membranous layer, which completes the osseo-fibrous case in which the Supraspinatus muscle is contained, affording attachment, by its inner surface, to some of the fibres of the muscle. It is thick internally, but thinner externally under the coraco-acromial ligament. When this fascia is removed, the Supraspinatus muscle is exposed.

The **Supraspinatus muscle** occupies the whole of the supraspinous fossa, arising from its internal two-thirds and from the strong fascia which covers its surface. The muscular fibres converge to a tendon which passes across the capsular ligament of the shoulder-joint, to which it is intimately adherent, and is inserted into the highest of the three facets on the great tuberosity of the humerus.

**Relations.**—By its upper surface, with the Trapezius, the clavicle, the acromion, the coraco-acromial ligament, and the Deltoid; by its under surface, with the scapula, the subscapular vessels and nerve, and upper part of the shoulder-joint.

The **Infraspinous fascia** is a dense fibrous membrane, covering in the Infraspinatus muscle and attached to the circumference of the infraspinous fossa; it affords attachment, by its inner surface, to some fibres of that muscle. At the point where the Infraspinatus commences to be covered by the Deltoid, this fascia divides into two layers: one layer passes over the Deltoid muscle, helping to form the Deltoid fascia already described; the other passes beneath the Deltoid to the shoulder-joint.

The **Infraspinus** is a thick, triangular muscle, which occupies the chief part of the infraspinous fossa, arising by fleshy fibres from its internal two-thirds, and by tendinous fibres from the ridges on its surface: it also arises from a strong fascia which covers it externally, and separates it from the Teres major and minor. The fibres converge to a tendon which glides over the external border of the spine of the scapula, and passing across the capsular ligament of the shoulder-
joint, is inserted into the middle facet on the great tuberosity of the humerus. The tendon of this muscle is occasionally separated from the spine of the scapula by a synovial bursa which communicates with the synovial cavity of the shoulder-joint.

**Relations.**—By its *posterior surface*, with the Deltoid, the Trapezius, Latissimus dorsi, and the integument; by its *anterior surface*, with the scapula, from which it is separated by the suprascapular and dorsalis scapulae vessels, and with the capsular ligament of the shoulder-joint. Its *lower border* is in contact with the Teres minor, occasionally united with it, and with the Teres major.

The **Teres minor** is a narrow, elongated muscle, which lies along the inferior border of the scapula. It arises from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminae, one of which separates this muscle from the Infraspinatus, the other from the Teres major; its fibres pass obliquely upward and outward, and terminate in a tendon which is inserted into the lowest of the three facets on the great tuberosity of the humerus, and, by fleshy fibres, into the humerus immediately below it. The tendon of this muscle passes across the capsular ligament of the shoulder-joint.

**Relations.**—By its *posterior surface*, with the Deltoid, and the integument; by its *anterior surface*, with the scapula, and dorsal branch of the subscapular artery, the long head of the Triceps, and the shoulder-joint; by its *upper border*, with the Infraspinatus; by its *lower border*, with the Teres major, from which it is separated anteriorly by the long head of the Triceps.

The **Teres major** is a broad and somewhat flattened muscle, which arises from the dorsal aspect of the inferior angle of the scapula, and from the fibrous septa interposed between it and the Teres minor and Infraspinatus; the fibres are
directed upward and outward, and terminate in a flat tendon, about two inches in length, which is inserted into the internal bicipital ridge of the humerus. The tendon of this muscle, at its insertion into the humerus, lies behind that of the Latissimus dorsi, from which it is separated by a synovial bursa, the two tendons being, however, united along their lower borders for a short distance.

**Relations.**—By its *posterior surface*, with the integument, from which it is separated, internally, by the Latissimus dorsi; and externally, by the long head of the Triceps; by its *anterior surface*, with the Subscapularis, Latissimus dorsi, Coraco-brachialis, short head of the Biceps, the axillary vessels, and brachial plexus of nerves. Its *upper border* is at first in relation with the Teres minor, from which it is afterward separated by the long head of the Triceps. Its *lower border* forms, in conjunction with the Latissimus dorsi, part of the posterior boundary of the axilla.

**Nerves.**—The Supra- and Infraspinatus-muscles are supplied by the suprascapular nerve; the Teres minor, by the circumflex; and the Teres major, by the lower subscapular.

**Actions.**—The Supraspinatus assists the Deltoid in raising the arm from the side, and fixes the head of the humerus in its socket. The Infraspinatus and Teres minor rotate the head of the humerus outward: when the arm is raised, they assist in retaining it in that position and carrying it backward. One of the most important uses of these three muscles is the great protection they afford to the shoulder-joint, the Supraspinatus supporting it above, and preventing displacement of the head of the humerus downward, while the Infraspinatus and Teres minor protect it behind, and prevent dislocation forward. The Teres major assists the Latissimus dorsi in drawing the humerus downward and backward, when previously raised, and rotating it inward; when the arm is fixed, it may assist the Pectoral and Latissimus dorsi muscles in drawing the trunk forward.

**THE ARM.**

**Anterior Humeral Region (Fig. 303).**

- Coraco-brachialis.
- Biceps.
- Brachialis anticus.

**Dissection.**—The arm being placed on the table, with the front surface uppermost, make a vertical incision through the integument along the middle line, from the outer extremity of the anterior fold of the axilla, to about two inches below the elbow-joint, where it should be joined by a transverse incision, extending from the inner to the outer side of the forearm; the two flaps being reflected on either side, the fascia should be examined (Fig. 301).

The deep fascia of the arm is continuous with that covering the shoulder and front of the great Pectoral muscle, by means of which it is attached, above, to the clavicle, acromion, and spine of the scapula; it forms a thin, loose, membranous sheath investing the muscles of the arm, sending down septa between them, and composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It differs in thickness at different parts, being thin over the Biceps, but thicker where it covers the Triceps, and over the condyles of the humerus: it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi on the inner side, and from the Deltoid externally. On either side it gives off a strong *intermuscular septum*, which is attached to the condylar ridge and condyle of the humerus. These septa serve to separate the muscles of the anterior from those of the posterior brachial region. The external intermuscular septum extends from the lower part of the external bicipital ridge, along the external condylar ridge, to the outer condyle; it is blended with the tendon of the Deltoid, gives attachment to the Triceps behind, to the Brachialis anticus, Supinator longus, and Extensor carpi radialis longior, in front; and is perforated by the musculo-spiral nerve and superior profunda artery. The internal intermuscular septum, thicker than the preceding, extends from the lower part of the internal lip of the bicipital groove below the Teres major, along the internal condylar ridge to the inner condyle; it is blended with the tendon of the Coraco-brachialis, and affords attachment to the Triceps behind, and the Brachialis anticus.
in front. It is perforated by the ulnar nerve and the inferior profunda and anastomotic arteries. At the elbow the deep fascia is attached to all the prominent points round the joint—viz. the condyles of the humerus and the olecran on process of the ulna—and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its inner side, in front of the internal intermuscular septum, is an oval opening in the deep fascia which transmits the basilic vein and some lymphatic vessels. On the removal of this fascia the muscles, vessels, and nerves of the anterior humeral region are exposed.

The Coraco-brachialis, the smallest of the three muscles in this region, is situated at the upper and inner part of the arm. It arises by fleshy fibres from the apex of the coracoid process, in common with the short head of the Biceps, and from the intermuscular septum between the two muscles; the fibres pass downward, backward, and a little outward, to be inserted by means of a flat tendon into a rough ridge at the middle of the inner surface and internal border of the shaft of the humerus between the origins of the Triceps and Brachialis anticus. It is perforated by the musculo-cutaneous nerve. The inner border of the muscle forms a guide to the position of the brachial artery in tying the vessel in the upper part of its course.

Relations.—By its anterior surface, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it; by its posterior surface, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the inner head of the Triceps, the humerus, and the anterior circumflex vessels; by its inner border, with the brachial artery, and the median and musculo-cutaneous nerves; by its outer border, with the short head of the Biceps and Brachialis anticus.

The Biceps (Biceps flexor cubiti) is a long fusiform muscle, occupying the whole of the anterior surface of the arm, and divided above into two portions or heads, from which circumstance it has received its name. The short head arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coraco-brachialis. The long head arises from the supraglenoid tubercle on the upper margin of the glenoid cavity, by a long rounded tendon, which is continuous with the glenoid ligament. This tendon arches over the head of the humerus, being enclosed in a special sheath of the synovial membrane of the shoulder-joint; it then passes through an opening in the capsular ligament at its attachment to the humerus, and descends in the bicipital groove, in which it is retained by a fibrous prolongation from the tendon of the Pectoralis major. The fibres from this tendon form a rounded belly, and, about the middle of the arm, join with the portion of the muscle derived from the short head. The belly of the muscle, narrow and somewhat flattened, terminates above the elbow in a flattened tendon, which is inserted into the back part of the tuberosity of the radius, a synovial bursa being interposed between the tendon and the front of the tuberosity. The tendon of the muscle is thin and broad; as it approaches the radius it becomes narrow and twisted upon itself, so that its external border becomes anterior, and its posterior flat surface is applied to the back of the tuberosity: opposite the bend of the elbow the tendon gives off, from its inner side, a broad aponeurosis, the bicipital fascia (semilunar fascia), which passes obliquely downward and inward across the brachial artery, and is continuous with the deep fascia of the forearm (Fig. 302). The inner border of this muscle forms a guide to the position of the vessel in tying the brachial artery in the middle of the arm.1

Relations.—Its anterior surface is overlapped above by the Pectoralis major and Deltoid; in the rest of its extent it is covered by the superficial and deep fasciae and the integument. Its posterior surface rests on the shoulder-joint and

1A third head to the Biceps is occasionally found (Theile says as often as once in eight or nine subjects), arising at the upper and inner part of the Brachialis anticus, with the fibres of which it is continuous, and inserted into the bicipital fascia and inner side of the tendon of the Biceps. In most cases this additional slip passes behind the brachial artery in its course down the arm. Occasionally the third head consists of two slips which pass down, one in front, the other behind the artery, concealing the vessel in the lower half of the arm.
humerus, from which it is separated by the Subscapularis, Teres major, Latissimus dorsi, Brachialis anticus, and the musculo-cutaneous nerve. Its inner border is in relation with the Coraco-brachialis, the brachial vessels, and median nerve; its outer border, with the Deltoid and Supinator longus.

The Brachialis anticus is a broad muscle, which covers the elbow-joint and the lower half of the front of the humerus. It is somewhat compressed from before backward, and is broader in the middle than at either extremity. It arises from the lower half of the outer and inner surfaces of the shaft of the humerus, and commences above at the insertion of the Deltoid, which it embraces by two angular processes. Its origin extends below, to within an inch of the margin of the articular surface, and is limited on each side by the external and internal borders of the shaft of the humerus. It also arises from the intermuscular septa on each side, but more extensively from the inner than the outer, from which it is separated below by the Supinator longus and Extensor carpi radialis longior. Its fibres converge to a thick tendon, which is inserted into a rough depression on the inferior surface of the coronoid process of the ulna, being received into an interval between two fleshy slips of the Flexor digitorum profundus.

Relations.—By its anterior surface, with the Biceps, the brachial vessels, musculo-entaneous, and median nerves; by its posterior surface, with the humerus and front of the elbow-joint; by its inner border, with the Triceps, ulnar nerve, and Pronator radii teres, from which it is separated by the intermuscular septum; by its outer border, with the musculo-spiral nerve, radial recurrent artery, the Supinator longus, and Extensor carpi radialis longior.

Nerves.—The muscles of this group are supplied by the musculo-cutaneous nerve, but the nerve to the Coraco-brachialis is often an independent branch of the outer cord of the Brachial plexus. The Brachialis anticus usually receives an additional filament from the musculo-spiral.

Actions.—The Coraco-brachialis draws the humerus forward and inward, and assists in elevating it. The Biceps is a flexor of the forearm: it is also a supinator, and makes tense the deep fascia of the forearm by means of the bicipital fascia. The Brachialis anticus is a flexor of the forearm, and protects the elbow-joint. When the forearm is fixed, the Biceps and Brachialis anticus flex the arm, as is seen in efforts of climbing.

Posterior Humeral Region.

Triceps. Subanconeus.

The Triceps (Triceps extensor cubiti) (Fig. 305) is situated on the back of the arm, extending the entire length of the posterior surface of the humerus. It is of large size, and divided above into three parts; hence its name. These three portions have been named (1) the middle, scapular, or long head; (2) the external, or long humeral; and (3) the internal, or short humeral head.

The middle or scapular head arises, by a flattened tendon, from a rough triangular depression immediately below the glenoid cavity, being blended at its upper part with the capsular ligament; the muscular fibres pass downward between the two other portions of the muscle, and join with them in the common tendon of insertion.

The external head arises from the posterior surface of the shaft of the humerus, between the insertion of the Teres minor and the upper part of the musculo-spiral groove; from the external border of the humerus and the external intermuscular septum: the fibres from this origin converge toward the common tendon of insertion.

The internal head arises from the posterior surface of the shaft of the humerus, below the groove for the musculo-spiral nerve; commencing above, narrow and pointed, below the insertion of the Teres major, and extending to within an inch of the troclear surface: it also arises from the internal border of the humerus and internal intermuscular septum. The fibres of this portion of the muscle are
directed, some downward to the olecranon, whilst others converge to the common tendon of insertion.

The common tendon of the Triceps commences about the middle of the back part of the muscle: it consists of two aponeurotic laminae, one of which is subcutaneous and covers the posterior surface of the muscle for the lower half of its extent; the other is more deeply seated in the substance of the muscle: after receiving the attachment of the muscular fibres, they join together above the elbow, and are inserted, for the most part, into the back part of the upper surface of the olecranon process; a band of fibres is, however, continued downward, on the outer side, over the Anconeus, to blend with the deep fascia of the forearm. A small bursa, occasionally multilocular, is situated on the front part of this surface, beneath the tendon.

The long head of the Triceps descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (Fig. 305). The triangular space contains the dorsalis scapulæ vessels; it is bounded by the Teres minor above, the Teres major below, and the scapular head of the Triceps externally; the quadrangular space transmits the posterior circumflex vessels and the circumflex nerve; it is bounded by the Teres minor above, the Teres major below, the scapular head of the Triceps internally, and the humerus externally.

Relations.—By its posterior surface, with the Deltoid above: in the rest of its extent it is subcutaneous; by its anterior surface, with the humerus, musculo-spiral nerve, superior profunda vessels, and back part of the elbow-joint. Its middle or long head is in relation, behind, with the Deltoid and Teres minor; in front, with the Subscapularis, Latissimus dorsi, and Teres major.

The Subanconeus is a name given to a few fibres from the lower part of the Triceps muscle, which are inserted into the posterior ligament of the elbow-joint. By some authors it is regarded as the analogue of the Suberureus in the lower limb, but it is not a separate muscle.

Nerves.—The Triceps is supplied by the musculo-spiral nerve.

Actions.—The Triceps is the great extensor muscle of the forearm, serving, when the forearm is flexed, to extend the elbow-joint. It is the direct antagonist of the Biceps and Brachialis anticus. When the arm is extended the long head of the muscle may assist the Teres major and Latissimus dorsi in drawing the humerus backward and in adducting it to the thorax. The long head of the Triceps protects the under part of the shoulder-joint, and prevents displacement of the head of the humerus downward and backward. The Subanconeus draws up the posterior ligament during extension of the forearm.

Surgical Anatomy.—The existence of the band of fibres from the Triceps to the fascia of the forearm is of importance in excision of the elbow, and should always be carefully preserved from injury by the operator, as by means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise mainly be accomplished by gravity; that is to say, allowing the forearm to drop from its own weight.

THE FOREARM.

Dissection.—To dissect the forearm, place the limb in the position indicated in Fig. 301; make a vertical incision along the middle line from the elbow to the wrist, and a transverse incision at the extremity of this; the superficial structures being removed, the deep fascia of the forearm is exposed.

The deep fascia of the forearm, continuous above with that enclosing the arm, is a dense, highly glistening aponeurotic investment, which forms a general sheath enclosing the muscles in this region; it is attached, behind, to the olecranon and posterior border of the ulna, and gives off from its inner surface numerous inter-muscular septa, which enclose each muscle separately. Below, it is continuous in front with the anterior annular ligament, and forms a sheath for the tendon of the Palmaris longus muscle, which passes over the annular ligament to be inserted into the palmar fascia. Behind, near the wrist-joint, it becomes much thickened
by the addition of many transverse fibres, and forms the posterior annular liga-
mament. It consists of circular and oblique fibres, connected together by numerous
vertical fibres. It is much thicker on the dorsal than on the palmar surface, and
at the lower than at the upper part of the forearm, and is strengthened by
tendinous fibres derived from the Brachialis anticus and Biceps in front, and from
the Triceps behind. Its inner surface gives origin to muscular fibres, especially
at the upper part of the inner and outer sides of the forearm, and forms the
boundaries of a series of conical-shaped cavities, in which the muscles are
contained. Besides the vertical septa separating each muscle, transverse septa are
given off both on the anterior and posterior surfaces of the forearm, separating the
depth from the superficial layer of muscles. Numerous apertures exist in the fascia
for the passage of vessels and nerves; one of these, of large size, situated at the
front of the elbow, serves for the passage of a communicating branch between the
superficial and deep veins.

The muscles of the forearm may be subdivided into groups corresponding to
the region they occupy. One group occupies the inner and anterior aspect of the
forearm, and comprises the Flexor and Pronator muscles. Another group occupies
its outer side, and a third its posterior aspect. The two latter groups include all
the Extensor and Supinator muscles.

**Anterior Radio-Ulnar Region.**

**Superficial Layer.**

Pronator radii teres.  
Flexor carpi radialis.  
Palmaris longus.

These muscles take origin from the internal condyle of the humerus by a
common tendon.

The **Pronator radii teres** arises by two heads. One, the larger and more
superficial, arises from the humerus, immediately above the internal condyle, and
from the tendon common to the origin of the other muscles; also from the fascia
of the forearm and intermuscular septum between it and the Flexor carpi radialis.
The other head is a thin fasciculus which arises from the inner side of the
coronoid process of the ulna, joining the preceding at an acute angle. Between
the two heads passes the median nerve. The muscle passes obliquely across the
forearm from the inner to the outer side, and terminates in a flat tendon, which
turns over the outer margin of the radius, and is inserted into a rough impression
at the middle of the outer surface of the shaft of that bone.

**Relations.**—By its anterior surface, with the deep fascia, the Supinator longus,
and the radial vessels and nerve; by its posterior surface, with the Brachialis
anticus, Flexor sublimis digitorum, the median nerve, and ulnar artery, the small
or deep head being interposed between the two latter structures. Its outer border
forms the inner boundary of a triangular space (cubital fossa) in which is placed
the brachial artery, median nerve, and tendon of the Biceps muscle. Its inner
border is in contact with the Flexor carpi radialis.

**Surgical Anatomy.**—This muscle, when suddenly brought into very active use, as in
the game of lawn tennis, is apt to be strained, producing slight swelling, tenderness, and pain on
putting the muscle into action. This is known as "lawn-tennis arm."

The **Flexor carpi radialis** lies on the inner side of the preceding muscle. It
arises from the internal condyle by the common tendon, from the fascia of the fore-
arm, and from the intermuscular septa between it and the Pronator radii teres, on
the outside, the Palmaris longus internally, and the Flexor sublimis digitorum
beneath. Slender and aponeurotic in structure at its commencement, it increases
in size, and terminates in a tendon which forms the lower two-thirds of its length.
This tendon passes through a canal on the outer side of the annular ligament,
runs through a groove in the os trapezium (which is converted into a canal by a
fibrous sheath, and lined by a synovial membrane), and is inserted into the base
of the metacarpal bone of the index finger, and by a slip into the base of the metacarpal bone of the middle finger. The radial artery lies between the tendon of this muscle and the Supinator longus, and may easily be tied in this situation.

**Relations.**—By its superficial surface, with the deep fascia and the integument; by its deep surface, with the Flexor sublimis digitorum. Flexor longus pollicis, and wrist-joint; by its outer border, with the Pronator radii teres and the radial vessels; by its inner border, with the Palmaris longus above and the median nerve below.

The **Palmaris longus** is a slender, fusiform muscle lying on the inner side of the preceding. It arises from the inner condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It terminates in a slender, flattened tendon which passes over the annular ligament to end in the palmar fascia, frequently sending a tendinous slip to the short muscles of the thumb. This muscle is often absent; or it may be tendinous above and muscular below; or muscular at both extremities of a middle tendon.

**Relations.**—By its deep surface, with the Flexor sublimis digitorum; internally, with the Flexor carpi ulnaris; externally, with the Flexor carpi radialis. The median nerve lies close to the tendon, just above the wrist, on its inner and posterior side.

The **Flexor carpi ulnaris** lies along the ulnar side of the forearm. It arises by two heads connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. One head arises from the inner condyle of the humerus by the common tendon; the other, from the inner margin of the olecranon by an aponeurosis which arises also from the upper two-thirds of the posterior border of the ulna, in common with the Extensor carpi ulnaris and the Flexor profundus digitorum; other fibres spring from the septum between it and the Flexor sublimis digitorum. The fibres terminate in a tendon which occupies the anterior part of the lower half of the muscle, and is inserted into the pisiform bone, and is prolonged from this to the fifth metacarpal and unciform bones by the piso-metacarpal and pisoulnar ligaments and to the annular ligament. The ulnar artery lies on the outer side of the tendon of this muscle, in the lower two-thirds of the forearm, the tendon forming a guide in tying the vessel in this situation.

**Relations.**—By its superficial surface, with the deep fascia, with which it is intimately connected for a considerable extent; by its deep surface, with the Flexor sublimis digitorum, the Flexor profundus digitorum, the Pronator quadratus, and the ulnar vessels and nerve; by its outer or radial border, with the Palmaris longus above, and the ulnar vessels and nerve below.

The **Flexor sublimis digitorum** (perforatus) is placed beneath the preceding muscles, which therefore must be removed in order to bring its attachment into view. It is the largest of the muscles of the superficial layer, and arises by three heads. One head arises from the internal condyle
of the humerus by the common tendon, from the internal lateral ligament of the elbow-joint, and from the intermuscular septum common to it and the preceding muscles. The second head arises from the inner side of the coronoid process of the ulna, above the ulnar origin of the Pronator radii teres (Fig. 200, p. 255). The third head arises from the oblique line and from a portion of the anterior border of the radius, extending to just below the insertion of the Pronator radii teres. The fibres pass vertically downward, forming a broad and thick muscle, which divides into four tendons about the middle of the forearm; as these tendons pass beneath the annular ligament into the palm of the hand they are arranged in pairs, the anterior pair corresponding to the middle and ring fingers, the posterior pair to the index and little fingers. The tendons diverge from one another as they pass onward. Opposite the base of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendons of the Flexor profundus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying deep flexor tendon. Finally they subdivide a second time, to be inserted into the sides of the second phalanges about their middle. After leaving the palm these tendons, accompanied by the deep flexor tendons, lie in osseo-aponeurotic canals formed by the fibrous sheath of the tendons and the bones (Fig. 816).

Relations.—In the forearm, by its superficial surface, with the deep fascia and all the preceding superficial muscles; by its deep surface, with the Flexor profundus digitorum. Flexor longus pollicis, the ulnar vessels and nerve, and the median nerve. In the hand its tendons are in relation, in front, with the palmar fascia, superficial palmar arch, and the branches of the median nerve; behind, with the tendons of the deep Flexor and the Lumbricales.

Fibrous Sheath of the Flexor Tendons.—The flexor tendons of the fingers as they run along the phalanges are retained against the bones by a fibrous sheath, forming osseo-aponeurotic canals. These sheaths are formed by strong fibrous bands which arch across the tendons and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely; but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane, which is reflected on the contained tendon.

Deep Layer.

Flexor profundus digitorum. Flexor longus pollicis.

Pronator quadratus.

Dissection.—Divide each of the superficial muscles at its centre, and turn either end aside; the deep layer of muscles, together with the median nerve and ulnar vessels, will then be exposed.

The Flexor profundus digitorum (perforans) (Fig. 307) is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It arises from the upper three-fourths of the anterior and inner surfaces of the shaft of the ulna, embracing the insertion of the Brachialis anticus above, and extending, below, to within a short distance of the Pronator quadratus. It also arises from a depression on the inner side of the coronoid process; by an aponeurosis from the upper three-fourths of the posterior border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The fibres form a fleshy belly of considerable size, which divides into four tendons: these pass under the annular ligament beneath the tendons of the Flexor sublimis digitorum. Opposite the first phalanges the tendons pass between the two slips of the tendons of the Flexor sublimis digitorum, and are finally inserted into the bases of the last phalanges. The tendon of the index finger is distinct; the rest are connected together by cellular tissue and tendinous slips as far as the palm of the hand. The tendons of this and those of the Flexor sublimis digitorum, whilst contained in the osseo-aponeurotic canals of the fingers, are invested in a synovial
sheath, and are connected to each other and to the phalanges by slender tendinous filaments, called vincula accessorii tendinum. One of these connects the deep tendon to the bone before it passes through the superficial tendon; a second connects the two tendons together, after the deep tendons have passed through; and a third connects the deep tendon to the head of the second phalanx. This last consists largely of yellow elastic tissue, and may assist in drawing down the tendon after flexion of the finger.¹

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles in that region.

**Relations.**—By its superficial surface, in the forearm, with the Flexor sublimis digitorum, the Flexor carpi ulnaris, the ulnar vessels and nerve, and the median nerve; and in the hand, with the tendons of the superficial Flexor; by its deep surface, in the forearm, with the ulna, the intersosseous membrane, the Pronator quadratus; and in the hand, with the interossei, Adductor pollicis, and deep palmar arch; by its ulnar border, with the Flexor carpi ulnaris; by its radial border, with the Flexor longus pollicis, the anterior intersosseous vessels and nerve being interposed.

The Flexor longus pollicis is situated on the radial side of the forearm, lying on the same plane as the preceding. It arises from the grooved anterior surface of the shaft of the radius, commencing above, immediately below the tuberosity and oblique line, and extending below to within a short distance of the Pronator quadratus. It also arises from the adjacent part of the interosseous membrane, and generally by a fleshy slip from the base of the coronoid process. The fibres pass downward, and terminate in a flattened tendon which passes beneath the annular ligament, is then lodged in the interspace between the outer head of the Flexor brevis pollicis and the Adductor obliquus pollicis, and entering an osseo-aponeurotic canal.

similar to those for the other flexor tendons, is inserted into the base of the last phalanx of the thumb.

**Relations.**—By its superficial surface, with the Flexor sublimis digitorum, Flexor carpi radialis, Supinator longus, and radial vessels; by its deep surface, with the radius, interosseous membrane, and Pronator quadratus; by its ulnar border, with the Flexor profundus digitorum, from which it is separated by the anterior interosseous vessels and nerve.

The **Pronator quadratus** is a small, flat, quadrilateral muscle, extending transversely across the front of the radius and ulna, above their carpal extremities. It arises from the oblique or pronator ridge on the lower part of the anterior surface of the shaft of the ulna; from the lower fourth of the anterior surface and the anterior border of the ulna; and from a strong aponeurosis which covers the inner third of the muscle. The fibres pass horizontally outward, to be inserted into the lower fourth of the anterior surface and anterior border of the shaft of the radius.

**Relations.**—By its superficial surface, with the Flexor profundus digitorum, the Flexor longus pollicis, Flexor carpi radialis, and the radial vessels; by its deep surface, with the radius, ulna, and interosseous membrane.

**Nerves.**—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar. Of the deep layer, the Flexor profundus digitorum is supplied conjointly by the ulnar and by the median through its branch, the anterior interosseous nerve, which also supplies the Flexor longus pollicis and Pronator quadratus.

**Actions.**—These muscles act upon the forearm, the wrist, and hand. The Pronator radii teres helps to rotate the radius upon the ulna, rendering the hand prone: when the radius is fixed it assists the other muscles in flexing the forearm. The Flexor carpi radialis is one of the flexors of the wrist; when acting alone it flexes the wrist, inclining it to the radial side. It can also assist in pronating the forearm and hand, and, by continuing its action, to bend the elbow. The Flexor carpi ulnaris is one of the flexors of the wrist: when acting alone it flexes the wrist, inclining it to the ulnar side, and, by continuing to contract, to bend the elbow. The Palmaris longus is a tensor of the palmar fascia. It also assists in flexing the wrist and elbow. The Flexor sublimis digitorum flexes the second phalanges. It assists in flexing the wrist and elbow. The Flexor profundus digitorum flexes the terminal phalanges (see page 497). After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one, but it cannot do so until after the contraction of the superficial muscle. It also assists in flexing the wrist. The Flexor longus pollicis is a flexor of the phalanges of the thumb. When the thumb is fixed it also assists in flexing the wrist. The Pronator quadratus helps to rotate the radius upon the ulna, rendering the hand prone.

**Radial Region (Fig. 308).**

Supinator longus. Extensor carpi radialis longior.
Extensor carpi radialis brevior.

**Dissection.**—Divide the integument in the same manner as in the dissection of the anterior brachial region, and, after having examined the cutaneous vessels and nerves and deep fascia, remove all those structures. The muscles will then be exposed. The removal of the fascia will be considerably facilitated by detaching it from below upward. Great care should be taken to avoid cutting across the tendons of the muscles of the thumb, which cross obliquely the larger tendons running down the back of the radius.

The **Supinator longus** is the most superficial muscle on the radial side of the forearm: it is fleshy for the upper two-thirds of its extent, tendinous below. It arises from the upper two-thirds of the external condyloid ridge of the humerus, and from the external intermuscular septum, being limited above by the
The muscles and fasciae.

484

Fig. 308.—Posterior surface of the forearm. Superficial muscles.

musculo-spiral groove. The fibres terminate above the middle of the forearm in a flat tendon which is inserted into the outer side of the base of the styloid process of the radius.

Relations.—By its superficial surface, with the integument and fascia for the greater part of its extent; near its insertion it is crossed by the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis; by its deep surface, with the humerus, the Extensor carpi radialis longior and brevior, the insertion of the Pronator radii teres, and the Supinator brevis; by its inner border, above the elbow, with the Brachialis anticus, the musculo-spiral nerve, and radial recurrent artery; and in the forearm with the radial vessels and nerve.

The Extensor carpi radialis longior is placed partly beneath the preceding muscle. It arises from the lower third of the external condyloid ridge of the humerus, and from the external intermuscular septum. The fibres terminate at the upper third of the forearm in a flat tendon, which runs along the outer border of the radius, beneath the extensor tendons of the thumb; it then passes through a groove common to it and the Extensor carpi radialis brevior, immediately behind the styloid process, and is inserted into the base of the metacarpal bone of the index finger, on its radial side.

Relations.—By its superficial surface, with the Supinator longus, and fascia of the forearm; its outer side is crossed obliquely by the extensor tendons of the thumb; by its deep surface, with the elbow-joint, the Extensor carpi radialis brevior, and back part of the wrist.

The Extensor carpi radialis brevior is shorter, as its name implies, and thicker than the preceding muscle, beneath which it is placed. It arises from the external condyle of the humerus by a tendon common to it and the three following muscles; from the external lateral ligament of the elbow-joint, from a strong aponeurosis which covers its surface, and from the intermuscular septa between it and the adjacent muscles. The fibres ter-
minate about the middle of the forearm in a flat tendon which is closely connected with that of the preceding muscle, and accompanies it to the wrist, lying in the same groove on the posterior surface of the radius; it passes beneath the extensor tendons of the thumb, then beneath the annular ligament, and, diverging somewhat from its fellow, is inserted into the base of the metacarpal bone of the middle finger, on its radial side.

The tendons of the two preceding muscles pass through the same compartment of the annular ligament, and are lubricated by a single synovial membrane, but are separated from each other by a small vertical ridge of bone as they lie in the groove at the back of the radius.

Relations.—By its superficial surface, with the Extensor carpi radialis longior, and with the Extensor muscles of the thumb which cross it; by its deep surface, with the Supinator brevis, tendon of the Pronator radii teres, radius, and wrist-joint; by its ulnar border, with the Extensor communis digitorum.

The Extensor communis digitorum is situated at the back part of the forearm. It arises from the external condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. Just below the middle of the forearm it divides into three tendons, which pass, together with the Extensor indicis, through a separate compartment of the annular ligament, lubricated by a synovial membrane. The tendons then diverge, the innermost one dividing into two; and all, after passing across the back of the hand, are inserted into the second and third phalanges of the fingers in the following manner: Each tendon becomes narrow and thickened opposite the metacarpo-phalangeal articulation, and gives off a thin fasciculus upon each side of the joint, which blends with the lateral ligaments and serves as the posterior ligament; after having passed the joint it spreads out into a broad aponeurosis, which covers the whole of the dorsal surface of the first phalanx, being reinforced, in this situation, by the tendons of the Interossei and Lumbricales. Opposite the first phalangeal joint this aponeurosis divides into three slips, a middle and two lateral: the former is inserted into the base of the second phalanx; and the two lateral, which are continued onward along the sides of the second phalanx, unite by their contiguous margins, and are inserted into the dorsal surface of the last phalanx. As the tendons cross the phalangeal joints they furnish them with posterior ligaments. The tendons of the middle, ring, and little fingers are connected together, as they cross the hand, by small, oblique, tendinous slips, or vincula; those on each side of the ring finger are strong, and bind the tendon of this finger closely to those of the middle and little finger, so that it cannot, in general, be freely extended without moving the other two. Sometimes there is also a thin slip between the tendons of the index and middle fingers. The tendons of the index and little fingers also receive, before their division, the special extensor tendons belonging to them.

Relations.—By its superficial surface, with the fascia of the forearm and hand, the posterior annular ligament, and integument; by its deep surface, with the Supinator brevis, the Extensor muscles of the thumb and index finger, the posterior interosseous vessels and nerve, the wrist-joint, carpus, metacarpus, and phalanges; by its radial border, with the Extensor carpi radialis brevior; by its ulnar border, with the Extensor minimi digiti and Extensor carpi ulnaris.

The Extensor minimi digiti is a slender muscle placed on the inner side of the Extensor communis, with which it is generally connected. It arises from the common tendon by a thin, tendinous slip, and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a separate
compartment in the annular ligament behind the inferior radio-ulnar joint, then divides into two as it crosses the hand, one slip being united to the common extensor by a cross-piece at the metacarpo-phalangeal articulation. Both finally spread into a broad aponeurosis which blends with the common extensor to the finger, and is inserted into the second and third phalanges. The tendon is situated on the ulnar side of, and somewhat more superficial than, the common extensor.

The Extensor carpi ulnaris is the most superficial muscle on the ulnar side of the forearm. It arises from the external condyle of the humerus by the common tendon; from the middle third of the posterior surface of the ulna, below the Anconeus, and by an aponeurosis from the posterior border of the ulna in common with the Flexor carpi ulnaris and the Flexor profundus digitorum; and from the deep fascia of the forearm. This muscle terminates in a tendon which runs through a groove behind the styloid process of the ulna, passes through a separate compartment in the annular ligament, and is inserted into the prominent tubercle on the ulnar side of the base of the metacarpal bone of the little finger.

Relations.—By its superficial surface, with the deep fascia of the forearm; by its deep surface, with the ulna and the muscles of the deep layer.

The Anconeus is a small triangular muscle placed behind and below the elbow-joint, and appears to be a continuation of the external portion of the Triceps. It arises by a separate tendon from the back part of the outer condyle of the humerus, and is inserted into the side of the olecranon and upper fourth of the posterior surface of the shaft of the ulna; its fibres diverge from their origin, the upper ones being directed transversely, the lower obliquely inward.

Relations.—By its superficial surface, with a strong fascia derived from the Triceps; by its deep surface, with the elbow-joint, the orbicular ligament, the ulna, and a small portion of the Supinator brevis.

Deep Layer (Fig. 310).

Supinator brevis. Extensor brevis pollicis.
Extensor ossis metacarpi pollicis. Extensor longus pollicis.
Extensor indicis.

The Supinator brevis is a broad muscle, of a hollow cylindrical form, curved round the upper third of the radius. It consists of two distinct planes of muscular fibres, between which lies the posterior interosseous nerve. The two planes arise in common: the superficial one by tendinous, and the deeper by muscular fibres from the external condyle of the humerus; from the external lateral ligament of the elbow-joint and the orbicular ligament of the radius; from the ridge on the ulna, which runs obliquely downward from the posterior extremity of the lesser sigmoid cavity; from the triangular depression in front of this ridge; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of the radius, and are inserted into the outer edge of the bicipital tuberosity and to the oblique line of the radius, as low down as the insertion of the Pronator radii teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is attached to the back part of its inner surface: the greater part of this portion of the muscle is inserted into the posterior and external surface of the shaft, midway between the oblique line and the head of the bone. Between the insertion of the two planes the posterior interosseous nerve lies on the shaft of the bone.

Relations.—By its superficial surface, with the superficial Extensor and Supinator muscles, and the radial vessels and nerve; by its deep surface, with the elbow-joint, the interosseous membrane, and the radius.

The Extensor ossis metacarpi pollicis is the most external and the largest of the deep extensor muscles: it lies immediately below the Supinator brevis, with which it is sometimes united. It arises from the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane,
and from the middle third of the posterior surface of the shaft of the radius. Passing obliquely downward and outward, it terminates in a tendon which runs through a groove on the outer side of the styloid process of the radius, accompanied by the tendon of the Extensor brevis pollicis, and is inserted into the base of the metacarpal bone of the thumb. It occasionally gives off two slips, near its insertion—one to the Trapezium, and the other to blend with the origin of the Abductor pollicis.

**Relations.**—By its superficial surface, with the Extensor communis digitorum, Extensor minimi digiti, and fascia of the forearm, and with the branches of the posterior interosseous artery and nerve which cross it; by its deep surface, with the ulna, interosseous membrane, radius, the tendons of the Extensor carpi radialis longior and brevior, which it crosses obliquely, and, at the outer side of the wrist, with the radial vessels; by its upper border, with the Supinator brevis; by its lower border, with the Extensor brevis pollicis.
The **Extensor brevis pollicis** (*Extensor primi internum pollicis*), the smallest muscle of this group, lies on the inner side of the preceding. It arises from the posterior surface of the shaft of the radius, below the Extensor ossis metacarpii pollicis, and from the interosseous membrane. Its direction is similar to that of the Extensor ossis metacarpi pollicis, its tendon passing through the same groove on the outer side of the styloid process, to be inserted into the base of the first phalanx of the thumb.

**Relations.**—The same as those of the Extensor ossis metacarpi pollicis.

The **Extensor longus pollicis** (*Extensor secundi internum pollicis*) is much larger than the preceding muscle, the origin of which it partly covers in. It arises from the posterior surface of the shaft of the ulna, below the origin of the Extensor ossis metacarpi pollicis, and from the interosseous membrane. It terminates in a tendon which passes through a separate compartment in the annular ligament, lying in a narrow, oblique groove at the back part of the lower end of the radius. It then crosses obliquely the tendons of the Extensor carpi radialis longior and brevior, being separated from the other extensor tendons of the thumb by a triangular interval, in which the radial artery is found, and is finally inserted into the base of the last phalanx of the thumb.

**Relations.**—By its superficial surface, with the same parts as the Extensor ossis metacarpi pollicis; by its deep surface, with the ulna, interosseous membrane, the posterior interosseous nerve, radius, the wrist, the radial vessels, and metacarpal bone of the thumb.

The **Extensor indicis** is a narrow, elongated muscle placed on the inner side of, and parallel with, the preceding. It arises from the posterior surface of the shaft of the ulna, below the origin of the Extensor longus pollicis and from the interosseous membrane. Its tendon passes with the Extensor communis digitorum through the same canal in the annular ligament, and subsequently joins the tendon of the Extensor communis which belongs to the index finger, opposite the lower end of the corresponding metacarpal bone, lying to the ulnar side of the tendon from the common Extensor.

**Relations.**—The relations are similar to those of the preceding muscles.

**Nerves.**—The Supinator longus, Extensor carpi radialis longior, and Anconeus are supplied by branches from the musculo-spiral nerve; the remaining muscles of the radial and posterior brachial regions, by the posterior interosseous nerve.

**Actions.**—The muscles of the radial and posterior brachial regions, which comprise all the extensor and supinator muscles, act upon the forearm, wrist, and hand; they are the direct antagonists of the pronator and flexor muscles. The Anconeus assists the Triceps in extending the forearm. The chief action of the Supinator longus is that of a flexor of the elbow-joint, but in addition to this it may act both as a supinator or a pronator; that is to say, if the forearm is forcibly pronated it will act as a supinator, and bring the bones into a position midway between supination and pronation; and, *vice versa*, if the arm is forcibly supinated, it will act as a pronator, and bring the bones into the same position, midway between supination and pronation. The action of the muscle is therefore to throw the forearm and hand into the position they naturally occupy when placed across the chest. The Supinator brevis is a supinator; that is to say, when the radius has been carried across the ulna in pronation and the back of the hand is directed forward, this muscle carries the radius back again to its normal position on the outer side of the ulna, and the palm of the hand is again directed forward. The Extensor carpi radialis longior extends the wrist and abducteds the hand. It may also assist in bending the elbow-joint; at all events, it serves to fix or steady this articulation. The *Extensor carpi radialis brevior* assists the Extensor carpi radialis longior in extending the wrist, and may also act slightly as an adductor of the hand. The Extensor carpi ulnaris helps to extend the hand, but when acting alone inclines it toward the ulnar side; by its continued action it extends the elbow-joint. The Extensor communis digitorum extends the phalanges, then the wrist, and finally the elbow. It acts principally on the proximal phalanges, the
middle and terminal phalanges being extended by the Interossei and Lumbricales. It has also a tendency to separate the fingers as it extends them. The Extensor minimi digiti extends similarly the little finger, and by its continued action it assists in extending the wrist. It is owing to this muscle that the little finger can be extended or pointed whilst the others are flexed. The chief action of the Extensor ossis metacarpi pollicis is to carry the thumb outward and backward from the palm of the hand, and hence it has been called the abductor longus pollicis. By its continued action it helps to extend and abduct the wrist. The Extensor brevis pollicis extends the proximal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor longus pollicis extends the terminal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor indicis extends the first phalanx of the index finger, and by its continued action assists in extending the wrist. It is owing to this muscle that the index finger can be extended or pointed while the others are flexed.

Surgical Anatomy.—The tendons of the Extensor muscles of the thumb are liable to become strained and their sheaths inflamed after excessive exercise, producing a sausage-shaped swelling along the course of the tendon, and giving a peculiar creaking sensation to the finger when the muscle acts. In consequence of its often being caused by such movements as wringing clothes, it is known as "washerwoman’s sprain."

THE HAND.

Dissection (Fig. 301).—Make a transverse incision across the front of the wrist, and a second across the heads of the metacarpal bones: connect the two by a vertical incision in the middle line, and continue it through the centre of the middle finger. The anterior and posterior annular ligaments and the palmar fascia should then be dissected.

The Anterior Annular Ligament is a strong, fibrous band which arches over the carpus, converting the deep groove on the front of the carpal bones into a canal, beneath which pass the flexor tendons of the fingers. It is attached, internally, to the pisiform bone and unciform process of the unciform bone, and externally to the tuberosity of the scaphoid and to the inner part of the anterior surface and the ridge on the trapezium. It is continuous, above, with the deep fascia of the forearm, of which it may be regarded as a thickened portion, and, below, with the palmar fascia. It is crossed by the ulnar vessels and nerve and the cutaneous branches of the median and ulnar nerves. At its outer extremity is the tendon of the Flexor carpi radialis, which lies in the groove on the trapezium between the attachments of the annular ligament to the bone. It has inserted into its anterior surface the tendon of the Palmaris longus and part of the tendon of the Flexor carpi ulnaris, and has arising from it, below, the small muscles of the thumb and little finger. Beneath it pass the tendons of the Flexor sublimis and profundus digitorum, the Flexor longus pollicis, and the median nerve.

The Synovial Membranes of the Flexor Tendons at the Wrist.—There are two synovial membranes which enclose all the tendons as they pass beneath this ligament—one for the Flexor sublimis and profundus digitorum, the other for the Flexor longus pollicis. They extend up into the forearm for about an inch above the annular ligament, and downward about halfway along the metacarpal bone, where they terminate in a blind diverticulum around each pair of tendons, with the exception of the thumb and sometimes the little finger—in these two fingers.
the diverticulum is continued on, and communicates with the synovial sheath of the tendons. In the other three fingers the synovial sheath of the tendons in the fingers begins as a blind pouch without communication with the large synovial sac (Fig. 313).

**Surgical Anatomy.**—This arrangement of the synovial sheaths explains the fact that thecal abscess in the thumb and little finger is liable to be followed by abscesses in the forearm, from extension of the inflammation along the continuous synovial sheaths. Ganglion is apt to occur in this situation, constituting "compound palmar ganglion": it presents an hour-glass outline, with a swelling in front of the wrist and in the palm of the hand, and a constriction corresponding to the annular ligament between the two. The fluid can be forced from the one swelling to the other under the ligament.

The **Posterior Annular Ligament** is a strong fibrous band extending transversely across the back of the wrist, and consisting of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It forms a sheath for the extensor tendons in their passage to the fingers, being attached, internally, to the styloid process of the ulna, the cuneiform and pisiform bones; externally, to the margin of the radius; and, in its passage across the wrist, to the elevated ridges on the posterior surface of the radius. It presents six compartments for the passage of tendons, each of which is lined by a separate synovial membrane. These are, from without inward—1. On the outer side of the styloid process, for the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis; 2. Behind the styloid process, for the tendons of the Extensor carpi radialis longior and brevior; 3. About the middle of the posterior surface of the radius, for the tendon of the Extensor longus pollicis; 4. To the inner side of the latter, for the tendons of the Extensor communis digitorum and Extensor indicis; 5. Opposite the interval between the radius and ulna, for the Extensor minimi digiti; 6. Grooving the back of the ulna, for the tendon of the Extensor carpi ulnaris.

The synovial membranes lining these sheaths are usually very extensive, reaching from above the annular ligament, down upon the tendons for a variable distance on the back of the hand.

The **deep palmar fascia** (Fig. 314) forms a common sheath which invests the muscles of the hand. It consists of a central and two lateral portions.

The **central portion** occupies the middle of the palm, is triangular in shape, of
great strength and thickness, and binds down the tendons in this situation. It is narrow above, being attached to the lower margin of the annular ligament, and receives the expanded tendon of the Palmaris longus muscle. Below, it is broad and expanded, and divides into four slips, for the four fingers. Each slip gives off superficial fibres, which are inserted into the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpo-phalangeal articulation, and those to the fingers passing into the skin at the transverse fold at the base of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the lateral margins of the anterior (glenoid) ligament of the metacarpo-phalangeal joint. From the sides of these processes offsets are sent backward, to be attached to the borders of the lateral surfaces of the metacarpal bones at their distal extremities. By this arrangement short channels are formed on the front of the lower ends of the metacarpal bones, through which the flexor tendons pass. Dr. W. W. Keen describes a fifth slip as frequently found passing to the thumb. The intervals left in the fascia between the four fibrous slips transmit the digital vessels and nerves and the tendons of the Lumbricales. At the points of division of the palmar fascia into the slips above mentioned numerous strong, transverse fibres bind the separate processes together. The palmar fascia is intimately adherent to the integument by dense fibro-areolar tissue, forming the superficial palmar fascia, and gives origin by its inner margin to the Palmaris brevis: it covers the superficial palmar arch, the
tendons of the flexor muscles, and the branches of the median and ulnar nerves, and on each side it gives off a vertical septum, which is continuous with the interosseous aponeurosis and separates the lateral from the middle palmar group of muscles.

The lateral portions of the palmar fascia are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger; they are continuous with the dorsal fascia, and in the palm with the central portion of the palmar fascia.

The Superficial Transverse Ligament of the Fingers is a thin, fibrous band which stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and internally to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass onward to their destination.

Surgical Anatomy.—The palmar fascia is liable to undergo contraction, producing a very inconvenient deformity known as "Dupuytren's contraction." The ring and little fingers are most frequently implicated, but the middle, the index, and the thumb may be involved. The proximal phalanx is drawn down and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

The Muscles of the Hand are subdivided into three groups: 1. Those of the thumb, which occupy the radial side; 2. Those of the little finger, which occupy the ulnar side; 3. Those in the middle of the palm and between the interosseous spaces.

Radial Region (Figs. 315, 316).

Muscles of the Thumb.

Abductor pollicis.
Opponens (Flexor ossis metacarpi) pollicis. Adductor obliquus pollicis.
Adductor transversus pollicis.

The Abductor pollicis is a thin, flat muscle placed immediately beneath the integument. It arises from the ridge of the os trapezium and annular ligament, and, passing outward and downward, is inserted by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb, sending a slip to join the tendon of the Extensor longus pollicis.

Relations.—By its superficial surface, with the palmar fascia; by its deep surface, with the Opponens pollicis, from which it is separated by a thin aponeurosis. Its inner border is separated from the Flexor brevis pollicis by a narrow cellular interval.

The Opponens pollicis is a small, triangular muscle placed beneath the preceding. It arises from the palmar surface of the trapezium and annular ligament, passes downward and outward, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

Relations.—By its superficial surface, with the Abductor pollicis; by its deep surface, with the trapezio-metacarpal articulation; by its inner border, with the Flexor brevis pollicis.

The Flexor brevis pollicis is much larger than either of the two preceding muscles, beneath which it is placed. It consists of two portions, outer and inner. The outer and more superficial portion arises from the trapezium and outer two-thirds of the annular ligament, and passes along the outer side of the tendon of the Flexor longus pollicis, and, becoming tendinous, has a sesamoid bone developed in its tendon, and is inserted into the outer side of the base of the first phalanx of the thumb. The inner and deeper portion of the muscle is very small, and arises from the ulnar side of the first metacarpal bone, and is inserted into the inner side of the base of the first phalanx with the Adductor obliquus pollicis. A sesamoid bone is developed in the common tendon of insertion.

Relations.—By its superficial surface, with the palmar fascia; by its deep sur-
face, with the tendon of the Flexor carpi radialis; by its external surface, with the Opponens pollicis; by its internal surface, with the Adductor obliquus pollicis.

The Adductor obliquus pollicis arises by several slips from the os magnum, the bases of the second and third metacarpal bones, the anterior annular ligament, and the sheath of the tendon of the Flexor carpi radialis. From this origin the greater number of fibres pass obliquely downward and converge to a tendon, which, uniting with the tendons of the deeper portion of the Flexor brevis pollicis and the Adductor transversus, is inserted into the inner side of the base of the first phalanx of the thumb, a sesamoid bone being developed in the tendon of insertion. A considerable fasciculus, however, passes more obliquely outward beneath the tendon of the long flexor to join the superficial portion of the short flexor and the Adductor pollicis. ¹

Relations.—By its superficial surface, with the Flexor longus pollicis and the outer head of the Flexor brevis pollicis. Its deep surface covers the Adductor transversus pollicis, and is in relation with the deep palmar arch, which passes between the two adductors.

The Adductor transversus pollicis (Fig. 315) is the most deeply seated of this group of muscles. It is of a triangular form, arising, by its broad base, from the lower two-thirds of the metacarpal bone of the middle finger on its palmar surface: the fibres, proceeding outward, converge, to be inserted, with the inner tendon of the Flexor brevis pollicis, and the Adductor obliquus pollicis, into the ulnar side of the base of the first phalanx of the thumb. From the common tendon of insertion a slip is prolonged to the Extensor longus pollicis.

Relations.—By its superficial surface, with the Adductor obliquus pollicis, the tendons of the Flexor profundus, and the Lumbricales. Its deep surface covers the first two interosseous spaces, from which it is separated by a strong aponeurosis.

Three of these muscles of the thumb, the Abductor, the Adductor transversus,

¹ This muscle was formerly described as the deep portion of the Flexor brevis pollicis.
and the Flexor brevis pollicis, at their insertions give off fibrous expansions which join the tendon of the Extensor longus pollicis. This permits of flexion of the proximal phalanx and extension of the terminal phalanx at the same time. These expansions, originally figured by Albinus, have been more recently described by M. Duchenne (Physiologie des Mouvements, page 299).

Nerves.—The Abductor, Opponens, and outer head of the Flexor brevis pollicis are supplied by the median nerve; the inner head of the Flexor brevis, and the Adductors, by the ulnar nerve.

Actions.—The actions of the muscles of the thumb are almost sufficiently indicated by their names. This segment of the hand is provided with three extensors—an extensor of the metacarpal bone, an extensor of the first, and an extensor of the second phalanx; these occupy the dorsal surface of the forearm and hand. There are also three flexors on the palmar surface—a flexor of the metacarpal bone, a flexor of the proximal, and a flexor of the terminal phalanx; there is also an Abductor and two Adductors. The Abductor pollicis moves the metacarpal bone of the thumb outward; that is, away from the index finger. The Flexor ossis metacarpi pollicis flexes the metacarpal bone—that is, draws it inward over the palm—and at the same time rotates the bone, so as to turn the ball of the thumb toward the fingers, thus producing the movement of opposition. The Flexor brevis pollicis flexes the proximal phalanx of the thumb. The Adductores pollicis move the metacarpal bone of the thumb inward; that is, toward the index finger. These muscles give to the thumb its extensive range of motion. It will be noticed, however, that in consequence of the position of the first metacarpal bone these movements differ from the corresponding movements of the metacarpal bones of the other fingers. Thus extension of the thumb more nearly corresponds to the motion of abduction in the other fingers, and flexion to adduction.

Ulnar Region (Fig. 316).

Palmaris brevis.

Muscules of the Little Finger.

Abductor minimi digiti.  Flexor brevis minimi digiti.

Opponens (Flexor ossis metacarpi) minimi digiti.

The Palmaris brevis is a thin quadrilateral muscle placed beneath the integument on the ulnar side of the hand. It arises by tendinous fasciculi from the annular ligament and palmar fascia; the fleshy fibres pass inward, to be inserted into the skin on the inner border of the palm of the hand.

Relations.—By its superficial surface, with the integument, to which it is intimately adherent, especially by its inner extremity; by its deep surface, with the inner portion of the palmar fascia, which separates it from the ulnar vessels and nerve, and from the muscles of the ulnar side of the hand.

The Abductor minimi digiti is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone, and terminates in a flat tendon which divides into two slips: one passes under the lateral expansion of the extensor tendon, opposite the metacarpo-phalangeal articulation, and is inserted into the ulnar side of the base of the first phalanx of the little finger. The other slip passes over the expansion, and is inserted into the ulnar border of the shaft of the same phalanx.

Relations.—By its superficial surface, with the inner portion of the palmar fascia, and the Palmaris brevis; by its deep surface, with the Flexor ossis metacarpi minimi digiti; by its outer border, with the Flexor brevis minimi digiti.

The Flexor brevis minimi digiti lies on the same plane as the preceding muscle, on its radial side. It arises from the tip of the unciform process of the unciform bone and anterior surface of the annular ligament, and is inserted into the base of the first phalanx of the little finger. It is separated from the Abductor at its origin by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is then, usually, of large size.
Relations.—By its superficial surface, with the internal portion of the palmar fascia, and the Palmaris brevis; by its deep surface, with the Opponens.

The Opponens minimi digiti (Fig. 307) is of a triangular form, and placed immediately beneath the preceding muscles. It arises from the unciform process of the unciform bone and contiguous portion of the annular ligament; its fibres pass downward and inward, to be inserted into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

Relations.—By its superficial surface, with the Flexor brevis and Abductor minimi digiti; by its deep surface, with the Interossei muscles in the fourth
metacarpal space, the metacarpal bone, and the Flexor tendons of the little finger.

Nerves.—All the muscles of this group are supplied by the ulnar nerve.

Actions.—The Abductor minimi digitii abducts the little finger from the middle line of the hand. It corresponds to a dorsal interosseous muscle. It also assists in flexing the proximal phalanx. The Flexor brevis minimi digitii abducts the little finger from the middle line of the hand. It also assists in flexing the proximal phalanx. The Opponens minimi digitii draws forward the fifth metacarpal bone, so as to deepen the hollow of the palm. The Palmaris brevis corrugates the skin on the inner side of the palm of the hand.

Middle Palmar Region.

Lumbricales. Interossei palmares.
Interossei dorsales.

The Lumbricales (Fig. 316) are four small fleshy fasciculi, accessories to the deep Flexor muscle. They arise by fleshy fibres from the tendons of the deep Flexor: the first and second, from the radial side and palmar surface of the tendons of the index and middle fingers; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. They pass to the radial side of the corresponding fingers, and opposite the metacarpophalangeal articulation each tendon terminates in a broad aponeurosis which is inserted into the tendinous expansion from the Extensor communis digitorum, covering the dorsal aspect of each finger.

The Interossei muscles are so named from occupying the intervals between the metacarpal bones. They are divided into two sets, a dorsal and palmar; the former are four in number, one in each metacarpal space; the latter, three in number, lie upon the metacarpal bones.

The Dorsal interossei are four in number, larger than the palmar, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from that side of the metacarpal bone which corresponds to the side of the finger in which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeurosis of the common extensor tendon. Between the double origin of each of these muscles is a narrow triangular interval, through the first of which passes the radial artery; through the other three passes a perforating branch from the deep palmar arch.

The First dorsal interosseous muscle, or Abductor indicis, is larger than the others. It is flat, triangular in form, and arises by two heads, separated by a fibrous arch, for the passage of the radial artery from the dorsum to the palm of the hand. The outer head arises from the upper half of the ulnar border of the first metacarpal bone; the inner head, from almost the entire length of the radial border of the second metacarpal bone; the tendon is inserted into the radial side of the index finger. The second and third dorsal interossei are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The fourth is inserted into the ulnar side of the ring finger.

The Palmar interossei, three in number, are smaller than the Dorsal, and placed upon the palmar surface of the metacarpal bones, rather than between them. They arise from the entire length of the metacarpal bone of one finger, and are inserted into the side of the base of the first phalanx and aponeurotic expansion of the common extensor tendon of the same finger.

The first arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the index finger. The second arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The third arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen
that each finger is provided with two Interossei muscles, with the exception of
the little finger, in which the Abductor muscle takes the place of one of the pair.

**Nerves.**—The two outer Lumbricales are supplied by the median nerve; the
rest of the muscles of this group, by the ulnar. All the Interossei are supplied by
the ulnar.

**Actions.**—The Palmar interossei muscles adduct the fingers to an imaginary
line drawn longitudinally through the centre of the middle finger; and the Dorsal
interossei abduct the fingers from that line. In addition to this, the Interossei, in
conjunction with the Lumbricales, *flex the first phalanges* at the metacarpo-phalan-
geal joints, and extend the second and third phalanges in consequence of their
insertion into the expansion of the extensor tendons. The *Extensor communis
digitorum* is believed to act almost entirely on the first phalanges.

**SURFACE FORM OF THE UPPER EXTREMITY.**

The *Pectoralis major* largely influences surface form and conceals a considerable part of the
thoracic wall in front. Its sternal origin presents a festooned border which bounds and deter-
mines the width of the sternal furrow. Its clavicular origin is somewhat depressed and flattened,
and between the two portions of the muscle is often an oblique depression which differentiates
the one from the other. The outer margin of the muscle is generally well marked above, and
bounds the infracavicular fossa, a triangular interval which separates the Pectoralis major from
the Deltoid. It gradually becomes less marked as it approaches the tendon of insertion, and
becomes more closely blended with the Deltoid muscle. The lower border of the Pectoralis
major forms the rounded anterior axillary fold, and corresponds with the direction of the fifth
rib. The *Pectoralis minor* influences surface form. When the arm is raised its lowest slip of
origin produces a local fulness just below the border of the anterior fold of the axilla, and so
serves to break the sharp line of the lower border of the Pectoralis major muscle, which is
produced when the arm is in this position. The origin of the *Serratus magnus* produces a very
characteristic surface marking. When the arm is raised from the side in a well-developed
subject, the five or six lower serrations are plainly discernible, forming a zigzag line, caused by
the series of digitations, which diminish in size from above downward, and have their apices
arranged in the form of a curve. When the arm is lying by the side, the first serration to
appear, at the lower margin of the Pectoralis major, is the one attached to the fifth rib. The
*Deltoid*, with the prominence of the upper extremity of the humerus, produces the rounded
outline of the shoulder. It is rounder and fuller in front than behind, where it presents a
somewhat flattened form. Its anterior border, above, presents a rounded, slightly curved
eminence, which bounds externally the infracavicular fossa; below, it is closely united with the

---

**Fig. 317.**—The Dorsal interosseous of left hand.  **Fig. 318.**—The Palmar interosseous of left hand.
Pectoralis major. Its posterior border is thin, flattened, and scarcely marked above; below, it is thicker and more prominent. When the muscle is in action, the middle portion becomes irregular, presenting alternate longitudinal elevations and depressions, the elevations corresponding to the fleshy portions, the depressions to the tendinous intersections of the muscle. The insertion of the Deltoid is marked by a depression on the outer side of the middle of the arm. Of the scapular muscles, the only one which materially influences surface form is the Teres major, which assists the Latissimus dorsi in forming the thick, rounded fold of the posterior boundary of the axilla. When the arm is raised, the Coraco-brachialis reveals itself as a long, narrow elevation which emerges from under cover of the anterior fold of the axilla and runs downward, internal to the shaft of the humerus. When the arm is hanging by the side, its front and inner part presents the prominence of the Biceps, bounded on either side by an intermuscular depression. This muscle forms the concave side of the front of the arm, and extends from the anterior margin of the axilla to the bend of the elbow. Its upper part is concealed by the Pectoralis major and the Deltoid, and its lower tendon sinks into the space at the bend of the elbow. When the muscle is in a state of complete contraction—that is to say, when the forearm has been flexed and supinated—it presents a rounded convex form, bulged out laterally, and its length is diminished. On each side of the Biceps, at the lower part of the arm, the Brachialis anticus is discernible. On the outer side it forms a narrow eminence which extends some distance up the arm along the border of the Biceps. On the inner side it shows itself only as a little fulness just above the elbow. On the back of the arm the long head of the Triceps may be seen as a longitudinal eminence emerging from under cover of the Deltoid, and gradually merging into the longitudinal flattened plane of the muscle on the lower part of the back of the arm. On the anterior aspect of the elbow are to be seen two muscular elevations, one on each side, separated above and converging below so as to form a triangular space. Of these, the inner elevation, consisting of the flexors and pronator, forms the prominence along the inner side and front of the forearm. It is a fusiform mass, pointed above at the internal condyle and gradually tapering off below. The Pronator radii teres, the innermost muscle of the group, forms the boundary of the triangular space at the bend of the elbow. It is shorter, less prominent, and more oblique than the outer boundary. The most prominent part of the eminence is produced by the Flexor carpi radialis, the muscle next in order on the inner side of the preceding one. It forms a rounded prominence above, and can be traced downward to its tendon, which can be felt lying on the front of the wrist, nearer to the radial than to the ulnar border, and to the inner side of the radial artery. The Palmaris longus presents no surface markings above, but below is the most prominent tendon on the front of the wrist, standing out, when the muscle is in action, as a sharp, tense cord beneath the skin. The Flexor sublimis digitorum does not directly influence surface form. The position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of the Palmaris longus and the Flexor carpi ulnaris. The Flexor carpi ulnaris occupies a small part of the posterior surface of the forearm, and is separated from the extensor and supinator group, which occupies the greater part of this surface, by the ulnar furrow, produced by the subcutaneous posterior border of the ulna. Its tendon can be perceived along the ulnar border of the front of the forearm, and is most marked when the hand is flexed and adducted. The deep muscles of the front of the forearm have no direct influence on surface form. The external group of muscles of the forearm, consisting of the extensors and supinators, occupies the outer and a considerable portion of the posterior surface of this region. They form a fusiform mass, which is altogether on a higher level than the pronato-flexor group. Its apex emerges from between the Triceps and Brachialis anticus muscles some distance above the elbow-joint, and acquires its greatest breadth opposite the external condyle, and thence gradually shades off into a flattened surface. About the middle of the forearm it divides into two longitudinal eminences which diverge from each other, leaving a triangular interval between them. The outer of these two groups of muscles consists of the Supinator longus and the Extensor carpi radialis longior et brevior, which form a longitudinal eminence descending from the external condyloid ridge in the direction of the styloid process of the radius. The other and more posterior group consists of the Extensor communis digitorum, the Extensor minimi digitii, and the Extensor carpi ulnaris. It commences above as a tapering form at the external condyle of the humerus, and is separated behind at its upper part from the Anconeus by a well-marked furrow, and below, from the pronato-flexor mass, by the ulnar furrow. In the triangular interval left between these two groups the extensors of the thumb and index finger are seen. The only two muscles of this region which require special mention as independently influencing surface form are the Supinator longus and the Anconeus. The inner border of the Supinator longus forms the outer boundary of the triangular space at the bend of the elbow. It commences as a rounded border above the condyle, and is longer, less oblique, and more prominent than the inner boundary. Lower down, the muscle forms a full fleshy mass on the outer side of the upper part of the forearm, and below tapers into a tendon, which may be traced down to the styloid process of the radius. The Anconeus presents a well-marked and characteristic surface form in the shape of a triangular, slightly elevated surface, immediately external to the subcutaneous posterior surface of the olecranon, and differentiated from the common extensor group by a well-marked oblique longitudinal depression. The upper angle of the triangle corresponds to the external condyle, and is marked by a depression or dimple in this situation. In the triangular interval caused by the divergence from each other of the two groups of muscles into which the extensor and supinator group is divided at the lower part of the forearm an
oblique elongated eminence is seen, caused by the emergence of two of the extensors of the thumb from their deep origin at the back of the forearm. This eminence, full above and becoming flattened out and partially subdivided below, runs downward and outward over the back and outer surface of the radius to the outer side of the wrist-joint, where it forms a ridge, especially marked when the thumb is extended, which passes onward to the posterior aspect of the thumb. The tendons of most of the extensor muscles are to be seen and felt at the level of the wrist-joint. Most externally are the tendons of the Extensor ossis metacarpis pollicis and the Extensor brevis pollicis, forming a vertical ridge over the outer side of the joint from the styloid process of the radius to the thumb. Internal to this is the oblique ridge produced by the tendon of the Extensor longus pollicis, very noticeable when the muscle is in action. The Extensor carpi radialis longior is scarcely to be felt, but the Extensor carpi radialis brevior can be distinctly perceived as a vertical ridge emerging from under the inner border of the tendon of the Extensor longus pollicis, when the hand is forcibly extended at the wrist. Internal to this, again, can be felt the tendons of the Extensor indicis, Extensor communis digitorum, and Extensor minimi digitii; the latter tendon being separated from those of the common extensor by a slight furrow. The muscles of the hand are principally concerned, as far as regards surface-form, in producing the thenar and hypothenar eminences, and individually are not to be distinguished, on the surface, from each other. The Adductor transversus pollicis is, however, an exception to this; its anterior border gives rise to a ridge across the web of skin connecting the thumb to the rest of the hand. The thenar eminence is much larger and rounder than the hypothenar one, which presents a longer and narrower eminence along the ulnar side of the hand. When the *Palmaris brevis* is in action it produces a wrinkling of the skin over the hypothenar eminence, and a deep dimple on the ulnar border of the hand. The anterior extremities of the *Lumbricalis muscles* help to produce the soft eminences just behind the clefts of the fingers, separated from each other by depressions corresponding to the flexor tendons in their sheaths.

Between the thenar and hypothenar eminences, at the wrist-joint, is a slight groove or depression, widening out as it approaches the fingers; beneath this we have the strong central part of the palmar fascia. Here we have some furrows, which are pretty constant in their arrangement, and bear some resemblance to the letter M. One of these furrows passes obliquely outward from the groove between the thenar and hypothenar regions to the head of the metacarpal bone of the index finger. A second passes inward, with a slight inclination upward, from the termination of the first to the ulnar side of the hand. A third runs parallel with the second and about three-quarters of an inch below it. Lastly, crossing these two latter furrows, is an oblique furrow parallel with the first. The skin of the palm of the hand differs considerably from that of the forearm. At the wrist it suddenly becomes hard and dense, and covered with a thick layer of cuticle. The skin in the thenar region presents these characteristics less than elsewhere. In spite of this hardness and density, the skin of the palm is exceedingly sensitive and very vascular. It is destitute of hair, and no sebaceous follicles have been found in this region. Over the fingers the skin again becomes thinner, especially at the flexures of the joints, and over the terminal phalanges it is thrown into numerous parallel ridges in consequence of the arrangement of the papillae in it. The superficial fascia in the palm is made up of two layers of fatty tissue. This tissue binds down the skin so firmly to the deep palmar fascia that very little movement is permitted between the two. On the back of the hand the *Dorsal interossei* produce elongated swellings between the metacarpal bones. The first dorsal interosseous (Abductor indicis), when the thumb is closely adducted to the hand, forms a prominent fusiform bulging; the other interossei are not so marked.

**SURGICAL ANATOMY OF THE UPPER EXTREMITY.**

The student, having completed the dissection of the muscles of the upper extremity, should consider the effects likely to be produced by the action of the various muscles in fracture of the bones.

In considering the actions of the various muscles upon fractures of the upper extremity, I have selected the most common forms of injury, both for illustration and description.

Fracture of the *middle of the clavicle* (Fig. 319) is always attended with considerable displacement: the inner end of the outer fragment is displaced inward and backward, while the outer end of the same fragment is rotated forward, owing to the displacement backward of its inner end. The whole outer fragment is somewhat depressed.

The displacement is produced as follows: *inward*, by the muscles passing from the chest to the outer fragment of the clavicle, to the scapula, and to the humerus—viz. the Subclavius, the Pectoralis minor and major, and the Latissimus dorsi; *backward*, with consequent rotation of the outer end of the outer fragment forward by the Pectoral muscles. The depression of the whole outer fragment is produced by the weight of the arm and by the contraction of the Deltoid. The outer end of the inner fragment appears to be elevated, the skin being drawn tensely over it; this is owing to the depression of the outer fragment, as the inner fragment is usually kept fixed by the costo-clavicular ligament and by the antagonism between the Sterno-mastoid and Pectoralis major muscles. But it may be raised by an unusually strong Sterno-mastoid, or by the inner end of the outer fragment getting below and behind it. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The outer fragment is to be drawn outward, and, together with the scapula, raised upward to a level with the inner fragment, and retained in that position.
THE MUSCLES AND FASCÉS.

In fracture of the acromial end of the clavicle, between the conoid and trapezoid ligaments, only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the sternal end, internal to the costo-clavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

Fracture of the acromion process usually arises from violence applied to the upper and outer part of the shoulder; it is generally known by the rotundity of the shoulder being lost, from the Deltoid drawing the fractured portion downward and forward; and the displacement may easily be discovered by tracing the margin of the clavicle outward, when the fragment will be found resting on the front and upper part of the head of the humerus. In order to relax the anterior and outer fibres of the Deltoid (the opposing muscle), the arm should be drawn forward across the chest and the elbow well raised, so that the head of the bone may press the acromion process upward and retain it in its position.

Fracture of the coracoïd process is an extremely rare accident, and is usually caused by a sharp blow on the point of the shoulder. Displacement is here produced by the combined actions of the Pectoralis major, and Deltoid, the head of the Biceps, and Coraco-brachialis, the forearm drawing the fragment inward, and the latter directly downward, the amount of displacement being limited by the connection of this process to the acromion by means of the coraco-acromial ligament. In order to relax these muscles and replace the fragments in close apposition, the forearm should be flexed so as to relax the Biceps, and the arm drawn forward and inward across the chest, so as to relax the Coraco-brachialis; the humerus should then be pushed upward against the coraco-acromial ligament, and the arm retained in that position.

Fracture of the surgical neck of the humerus (Fig. 320) is very common, is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment is slightly elevated under the coraco-acromial ligament by the muscles attached to the greater and lesser tuberosities; the lower fragment is drawn inward by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely outward from the side by the Deltoid, and occasionally elevated so as to project beneath and in front of the coracoïd process. The deformity is reduced by fixing the shoulder and drawing the arm outward and downward. To counteract the opposing muscles, and to keep the fragments in position, the arm should be drawn from the side and pasteboard splints applied on its four sides; a large conical-shaped pad should be placed in the axilla, with the base turned upward and the elbow approximated to the side, and retained there by a broad roller passed round the chest; the forearm should then be flexed, and the hand supported in a sling, care being taken not to raise the elbow, otherwise the lower fragment may be displaced upward.

In fracture of the shaft of the humerus below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoid, there is also considerable deformity; the upper fragment being drawn inward by the first-mentioned muscles, and the lower fragment upward and outward by the Deltoid, producing shortening of the limb, and a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture takes place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and retained in that position by adopting the same means as in the preceding injury.

In fractures of the shaft of the humerus immediately below the insertion of the Deltoid, the amount of deformity depends greatly upon the direction of the fracture. If it occurs in a transverse direction, only slight displacement takes place; the upper fragment being drawn a little forward; but in oblique fracture the combined actions of the Biceps and Brachialis anticus muscles in front and the Triceps behind draw upward the lower fragment, causing it to glide over the upper fragment, either backward or forward, according to the direction of the fracture. Simple extension reduces the deformity, and the application of splints on the four sides of the arm will retain the fragments in apposition.
Care should be taken not to raise the elbow, but the forearm and hand may be supported in a sling.

Fracture of the humerus (Fig. 321) immediately above the condyles deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backward. If the direction of the fracture is oblique from above, downward and forward, the lower fragment is drawn upward and backward by the Brachialis anticus and Biceps in front and the Triceps behind. This injury may be diagnosed from dislocation by the increased mobility in fracture, the existence of crepitus, and the fact of the deformity being remedied by extension, on the discontinuance of which it is reproduced. The age of the patient is of importance in distinguishing this form of injury from separation of the epiphysis. If fracture occurs in the opposite direction to that shown in the accompanying figure, the lower fragment is drawn upward and forward, causing a considerable prominence in front, and the upper fragment projects backward beneath the tendon of the Triceps muscle.

Fracture of the olecranon process (Fig. 322) is a frequent accident. The detached fragment is displaced upward, by the action of the Triceps muscle, from half an inch to two inches; the prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the lower fragment. The treatment consists in relaxing the Triceps by extending the limb, and retaining it in the extended position by means of a long straight splint applied to the front of the arm; the fragments are thus brought into close apposition, and may be further approximated by drawing down the upper fragment. Union is generally ligamentous.

Fracture of the neck of the radius is an exceedingly rare accident, and is generally caused by direct violence. Its diagnosis is somewhat obscure, on account of the slight deformity visible, the injured part being surrounded by a large number of muscles; but the movements of pronation and supination are entirely lost. The upper fragment is drawn outward by the Supinator brevis, its extent of displacement being limited by the attachment of the orbicular ligament. The lower fragment is drawn forward and slightly upward by the Biceps, and inward by the Pronator radii teres, its displacement forward and upward being counteracted in some degree by the Supinator brevis. The treatment essentially consists in relaxing the Biceps, Supinator brevis, and Pronator radii teres muscles by flexing the forearm, and placing it in a position midway between pronation and supination, extension having been previously made so as to bring the parts in apposition.

In fracture of the radius (Fig. 323) near its centre, the upper fragment is drawn upward by the Biceps and inward by the Pronator radii teres, holding a position midway between pronation and supination, and a degree of fullness in the upper half of the forearm is thus produced: the lower fragment is drawn downward and inward toward the ulna by the Pronator quadratus, and thrown into a state of pronation by the same muscle; at the same time, the Supinator longus, by elevating the styloid process into which it is inserted, will serve to depress the upper end of the lower fragment still more toward the ulna. In order to relax the opposing muscles the forearm should be bent, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow: well-padded splints should be applied on both sides of the forearm from the elbow to the wrist; the hand being allowed to fall; will, by its own weight, counteract the action of the Pronator quadratus and Supinator longus, and elevate the lower fragment to the level of the upper one.

In fracture of the shaft of the ulna the upper fragment retains its usual position, but the lower fragment is drawn outward toward the radius by the Pronator quadratus, producing a well-marked depression at the seat of fracture and some fullness on the dorsal and palmar surfaces of the forearm. The fracture is easily reduced by extension from the wrist and forearm. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.
In fracture of the shafts of the radius and ulna together the lower fragments are drawn upward, sometimes forward, sometimes backward, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fullness on the dorsal or palmar surface of the forearm; at the same time the two fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation: the upper fragment of the radius is drawn upward and inward by the Biceps and Pronator radii teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis anticus. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

In fracture of the lower end of the radius (Fig. 324) the displacement which is produced is very considerable, and bears some resemblance to dislocation of the carpus backward, from which it should be carefully distinguished. The lower fragment is drawn upward and backward behind the upper fragment by the combined actions of the Supinator longus and the flexors and the extensors of the thumb and carpus, producing a well-marked prominence on the back of the wrist, with a deep depression above it. The upper fragment projects forward, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the anterior surface of the forearm, immediately above the carpus, from the flexor tendons being thrust forward. This fracture may be distinguished from dislocation by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected; at the same time, on extension being discontinued, the parts immediately resume their deformed appearance (see also page 232). The age of the patient will also assist in determining whether the injury is fracture or separation of the epiphysis. The treatment consists in flexing the forearm, and making powerful extension from the wrist and elbow, depressing at the same time the radial side of the hand, and retaining the parts in that position by well-padded pistol-shaped splints.

**MUSCLES AND FASCIAE OF THE LOWER EXTREMITY.**

The Muscles of the Lower Extremity are subdivided into groups, corresponding with the different regions of the limb.

**ILIAC REGION.**
- Psoas magnus.
- Psoas parvus.
- Iliacus.

**THIGH.**
- Anterior Femoral Region.
  - Tensor vaginae femoris.
  - Sartorius.
  - Rectus.
  - Vastus externus.
  - Vastus internus.
  - Gracilis.
  - Internus.

**Internal Femoral Region.**
- Gracilis.
- Pectineus.
- Adductor longus.
- Adductor brevis.
- Adductor magnus.

**HIP.**
- Gluteal Region.
  - Gluteus maximus.
  - Gluteus medius.
  - Gluteus minimus.
  - Pyriformis.
THE Iliac Region.

Dissection.—No detailed description is required for the dissection of these muscles. On the removal of the viscera from the abdomen they are exposed, covered by the peritoneum and a thin layer of fascia, the iliac fascia.

The iliac fascia\(^1\) is the aponeurotic layer which lines the back part of the abdominal cavity, and covers the Psoas and Iliacus muscles throughout their whole extent. It is thin above, and becomes gradually thicker below as it approaches the crural arch. It is a part of the general fascia transversalis.

The portion covering the Psoas is attached, above, to the ligamentum arcuatum internum; internally, by a series of arched processes to the intervertebral substances and prominent margins of the bodies of the vertebrae, and to the upper part of the sacrum, the intervals so left, opposite the constricted portions of the bodies, transmitting the lumbar arteries and filaments of the sympathetic nerve. Externally, above the crest of the ilium, this portion of the iliac fascia is continuous with the anterior lamella of the lumbar fascia (see page 433), but below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The portion investing the Iliacus is connected externally to the whole length of the inner border of the crest of the ilium, and internally to the brim of the true pelvis or iliac portion of the ilio-pectineal line, and at the ilio-pectineal eminence it receives the tendon of insertion of the Psoas parvus, when that muscle exists. External to the femoral vessels, this fascia is intimately connected to the posterior margin of Poupart’s ligament, and is continuous with the fascia transversalis. Internal to the vessels it is attached to the ilio-pectineal line behind the conjoined tendon, where it is again continuous with the transversalis fascia; and,\n
\(^1\) The student must not confound this fascia with the iliac portion of the fascia lata (see p. 508).
corresponding to the point where the femoral vessels pass into the thigh, this fascia descends behind them, forming the posterior wall of the crural sheath. This portion of the iliac fascia which passes behind the femoral vessels is also attached to the ilio-pectineal line beyond the limits of the attachment of the conjoined tendon; at this part it is continuous with the pubic portion of the fascia lata of the thigh. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus behind it; it is separated from the peritoneum by a quantity of loose areolar tissue.

The Psoas magnus (Fig. 326) is a long fusiform muscle placed on the side of the lumbar region of the spine and margin of the pelvis. It arises from the front of the bases and lower borders of the transverse processes of the lumbar vertebrae by five fleshy slips; also from the sides of the bodies and the corresponding intervertebral substances of the last dorsal and all the lumbar vertebrae. The muscle is connected to the bodies of the vertebrae by five slips; each slip is attached to the upper and lower margins of two vertebrae, and to the intervertebral substance between them, the slips themselves being connected by the tendinous arches which extend across the constricted part of the bodies, and beneath which pass the lumbar arteries and sympathetic nerves. These tendinous arches also give origin to muscular fibres, and protect the blood-vessels and nerves from pressure during the action of the muscle. The first slip is attached to the contiguous margins of the last dorsal and first lumbar vertebrae; the last to the contiguous margins of the fourth and fifth lumbar, and to the intervertebral substance. From these points the muscle passes down across the brim of the pelvis, and, diminishing gradually in size, passes beneath Poupart’s ligament, and terminates in a tendon which, after receiving the fibres of the Iliacus, is inserted into the lesser trochanter of the femur.

Relations.—In the lumbar region: by its anterior surface, which is placed behind the peritoneum, with the iliac fascia, the ligamentum arcuatum internum, the kidney, Psoas parvus, renal vessels, ureter, spermatic vessels, genito-crural nerve, and the colon; by its posterior surface, with the transverse processes of the lumbar vertebrae and the Quadratus lumborum, from which it is separated by the anterior lamella of the lumbar fascia. The anterior crural nerve is at first situated in the substance of the muscle, and emerges from its outer border at the lower part. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its inner side the muscle is in relation with the bodies of the lumbar vertebrae, the lumbar arteries, the ganglia of the sympathetic nerve, and their branches of communication with the spinal nerves; the lumbar glands; the vena cava inferior on the right and the aorta on the left side, and along the brim of the pelvis with the external iliac artery. In the thigh it is in relation, in front, with the fascia lata; behind, with the capsular ligament of the hip, from which it is separated by a synovial bursa, which frequently communicates with the cavity of the joint through an opening of variable size; by its inner border, with the Pectineus and the femoral artery, which slightly overlaps it; by its outer border, with the anterior crural nerve and Iliacus muscle.

The Psoas parvus is a long slender muscle placed in front of the Psoas magnus. It arises from the sides of the bodies of the last dorsal and first lumbar vertebrae and from the intervertebral substance between them. It forms a small flat muscular bundle, which terminates in a long flat tendon inserted into the ilio-pectineal eminence, and, by its outer border, into the iliac fascia. This muscle is often absent, and, according to Cruveilhier, sometimes double.

Relations.—It is covered by the peritoneum, and, at its origin, by the ligamentum arcuatum internum; it rests on the Psoas magnus.

The Iliacus is a flat, triangular muscle which fills up the whole of the iliac fossa. It arises from the upper two-thirds of this fossa and from the inner margin of the crest of the ilium; behind, from the ilio-lumbar ligament and base of the sacrum; in front, from the anterior superior and anterior inferior spinous processes of the ilium, from the notch between them, and by a few fibres from the capsule.
of the hip-joint. The fibres converge to be inserted into the outer side of the tendon of the Psoas, some of them being prolonged into the oblique line which extends from the lesser trochanter to the linea aspera.

Relations.—Within the pelvis: by its anterior surface, with the iliac fascia, which separates the muscle from the peritoneum, and with the external cutaneous nerve; on the right side, with the cæcum; on the left side, with the sigmoid flexure of the colon; by its posterior surface, with the iliac fossa; by its inner border, with the Psoas magnus and anterior crural nerve. In the thigh, it is in relation, by its anterior surface, with the fascia lata, Rectus, and Sartorius; behind, with the capsule of the hip-joint, a synovial bursa common to it and the Psoas magnus being interposed.

Nerves.—The Psoas magnus, and the Psoas parvus when it exists, are supplied by the anterior branches of the lumbar nerves; the Iliacus by the anterior crural.

Actions.—The Psoas and Iliacus muscles, acting from above, flex the thigh upon the pelvis, and, at the same time, rotate the femur outward, from the obliquity of their insertion into the inner and back part of that bone. Acting from below, the femur being fixed, the muscles of both sides bend the lumbar portion of the spine and pelvis forward. They also serve to maintain the erect position, by supporting the spine and pelvis upon the femur, and assist in raising the trunk when the body is in the recumbent posture.

The Psoas parvus is a tensor of the iliac fascia.

Surgical Anatomy.—In the iliac fascia there is no definite septum between the portions of fascia covering the Psoas and Iliacus respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When abscess forms beneath this fascia, as it is very apt to do, the matter is contained in an osseo-fibrous cavity which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscle into the thigh.

Abscess within the sheath of the Psoas muscle (Psoas abscess) is generally due to tubercular caries of the bodies of the lower dorsal and lumbar vertebrae. When the disease is in the dorsal region, the matter tracts down the posterior mediastinum, in front of the bodies of the vertebrae, and, passing beneath the ligamentum arcuatum internum, enters the sheath of the Psoas muscle, down which it passes as far as the pelvic brim; it then gets beneath the iliac portion of the fascia and fills up the iliac fossa. In consequence of the attachment of the fascia to the pelvic brim, it rarely finds its way into the pelvis, but passes by a narrow opening under Poupart's ligament into the thigh, to the outer side of the femoral vessels. It thus follows that a Psoas abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the Psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under Poupart's ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebrae are the seat of the disease, the matter finds its way directly into the substance of the muscle. The muscular fibres are destroyed, and the nervous cords contained in the abscess are isolated and exposed in its interior; the femoral vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All Psoas abscesses do not, however, pursue this course; the matter may leave the muscle above the crest of the ilium, and, tracking backward, may point in the loin (lumbar abscess); or it may point above Poupart's ligament in the inguinal region; or it may follow the course of the iliac vessels into the pelvis, and, passing through the great saphenian notch, discharge itself on the back of the thigh; or it may open into the bladder or find its way into the perineum.

THE THIGH.

Anterior Femoral Region.

Tensor vamæ femoris. Vastus externus.
Sartorius. Vastus internus.
Rectus. Crureus.

Subcrureus.

Dissection.—To expose the muscles and fasciae in this region, make an incision along Poupart's ligament, from the anterior superior spine of the ilium to the spine of the os pubis; a vertical incision from the centre of this, along the middle of the thigh to below the knee-joint; and a transverse incision from the inner to the outer side of the leg, at the lower end of the vertical incision. The flaps of integument having been removed, the superficial and deep fasciae

1The Psoas and Iliacus are sometimes regarded as a single muscle, the Ilio-psoas, having two heads of origin and a single insertion.
should be examined. The more advanced student should commence the study of this region by an examination of the anatomy of femoral hernia and Scarpa's triangle, the incisions for the dissection of which are marked out in the figure below.

The superficial fascia forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb: in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these two layers, the superficial, is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a very thin, fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below Poupart's ligament. It covers the saphenous opening in the fascia lata, being closely united to its circumference, and is connected to the sheath of the femoral vessels, corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the cribiform fascia, the openings for these vessels having been likened to the holes in a sieve. The cribiform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as part of the fascia lata, but is usually considered (as in this work) as belonging to the superficial fascia. It is not until the cribiform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. Mr. Callender, however, speaks of cases in which, probably as the result of pressure from enlarged inguinal lymphatic glands, the fascia has become atrophied, and a saphenous opening exists independent of dissection. A femoral hernia in passing through the saphenous opening receives the cribiform fascia as one of its coverings. A large subcutaneous bursa is found in the superficial fascia over the patella.

The deep fascia of the thigh is exposed on the removal of the superficial fascia, and is named, from its great extent, the fascia lata; it forms a uniform investment for the whole of this region of the limb, but varies in thickness in different parts; thus, it is thicker in the upper and outer part of the thigh, where it receives a fibrous expansion from the Gluteus maximus muscle, and the Tensor vaginae femoris is inserted between its layers: it is very thin behind, and at the upper and inner part where it covers the Adductor muscles, and again becomes stronger around the knee, receiving fibrous expansions from the tendon of the Biceps externally, and from the Sartorius internally, and Quadriceps extensor cruris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; externally, to the crest of the ilium; in front, to Poupart's ligament and to the body of the os pubis; and internally, to the descending ramus.
of the os pubis, to the ascending ramus and tuberosity of the ischium, and to the lower border of the great sacro-sciatic ligament. From its attachment to the crest of the ilium it passes down over the Gluteus medius muscle to the upper border of the Gluteus maximus, where it splits into two layers, one passing superficial to and the other beneath this muscle. At the lower border of the muscle the two layers unite. Externally, just below the great trochanter, the fascia lata receives the greater part of the tendon of insertion of the Gluteus maximus, and becomes proportionately thickened. The portion of the fascia lata arising from the front part of the crest of the ilium, corresponding to the origin of the Tensor vaginae femoris, passes down the outer side of the thigh as two layers, one superficial and the other beneath this muscle; these at its lower end become blended together into a thick and strong band, having first received the insertion of the muscle. This band is continued downward, under the name of the ilio-tibial band, to be inserted into the external tuberosity of the tibia. Below, the fascia lata is attached to all the prominent points around the knee-joint—viz. the condyles of the femur, tuberosities of the tibia, and head of the fibula. On each side of the patella it is strengthened by transverse fibres given off from the lower part of the Vasti muscles, which are attached to and support this bone. Of these the outer is the stronger, and is continuous with the ilio-tibial band. From the inner surface of the fascia lata are given off two strong intermuscular septa, which are attached to the whole length of the linea aspera and its prolongations above and below: the external and stronger one, which extends from the insertion of the Gluteus maximus to the outer condyle, separates the Vastus externus in front from the short head of the Biceps behind, and gives partial origin to these muscles; the inner one, the thinner of the two, separates the Vastus internus from the Adductor and Pectineus muscles. Besides these there are numerous smaller septa, separating the individual muscles and enclosing each in a distinct sheath. At the upper and inner part of the thigh, a little below Poupart’s ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared off: it transmits the internal saphenous vein and other smaller vessels, and is termed the saphenous opening. In order more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the

Fig. 326.—Muscles of the iliac and anterior femoral regions.
thigh is described as consisting of two portions—an iliac portion and a pubic portion.

The **iliac portion** is all that part of the fascia lata on the outer side of the saphenous opening. It is attached, externally, to the crest of the ilium and its anterior superior spine, to the whole length of Poupart's ligament as far internally as the spine of the os pubis, and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the boundary or *falciform process* (*superior cornu*) of the saphenous opening; this margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels: to its edge is attached the cribriform fascia; and, below, it is continuous with the pubic portion of the fascia lata.

The **pubic portion** is situated at the inner side of the saphenous opening; at the lower margin of this aperture it is continuous with the iliac portion; traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the iliac fascia. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels, and the pubic portion behind them, so that an apparent aperture exists between the two, through which the internal saphenous joins the femoral vein.1

The fascia should now be removed from the surface of the muscles. This may be effected by pinching it up between the forefingers, dividing it, and separating it from each muscle in the course of its fibres.

The **Tensor vaginae femoris** arises from the anterior part of the outer lip of the crest of the ilium, and from the outer surface of the anterior superior spinous process, between the Glutens medius and Sartorius. It is inserted into the fascia lata about one-fourth down the outer side of the thigh. From the point of insertion the fascia is continued downward to the head of the tibia as a thickened band, the *iliotibial band*.

**Relations.**—By its *superficial surface*, with the fascia lata and the integument; by its *deep surface*, with the Glutens medius, Rectus femoris, Vastus externus, and the ascending branches of the external circumflex artery; by its *anterior border*, with the Sartorius, from which it is separated below by a triangular space, in which is seen the Rectus femoris; by its *posterior border*, with the Glutens medius.

The **Sartorius**, the longest muscle in the body, is flat, narrow, and ribbon-like; it arises by tendinous fibres from the anterior superior spinous process of the ilium and the upper half of the notch below it, passes obliquely across the upper and anterior part of the thigh, from the outer to the inner side of the limb, then descends vertically, as far as the inner side of the knee, passing behind the inner condyle of the femur, and terminates in a tendon which, curving obliquely forward, expands into a broad aponeurosis inserted into the upper part of the inner surface of the shaft of the tibia, nearly as far forward as the crest. This expansion is inserted into the bone by an inverted U-shaped aponeurosis: part of it is inserted behind the attachment of the Gracilis and Semitendinosus, and another part, arching over the upper border of the tendon of the Gracilis, is inserted into the tibia in front of these muscles. An offset is derived from the upper margin of this aponeurosis, which blends with the fibrous capsule of the knee-joint, and another, given off from its lower border, blends with the fascia on the inner side of the leg.

The relations of this muscle to the femoral artery should be carefully examined, as it constitutes the chief guide in tying the artery. In the upper third of the thigh it forms the outer side of a triangular space, *Scarpa's triangle*, the inner

---

1 These parts will be again more particularly described with the anatomy of Hernia.
side of which is formed by the Adductor longus, and the base, turned upward, by Poupart's ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh the femoral artery lies first along the inner border, and then behind the Sartorius.

**Relations.**—By its superficial surface, with the fascia lata and integument; by its deep surface, with the Rectus, Iliacus, Psoas, Vastus internus, anterior crural nerve, sheath of the femoral vessels, Adductor longus, Adductor magnus, Gracilis, Semitendinosus, long saphenous nerve, and internal lateral ligament of the knee-joint.

The **Quadriceps extensor** includes the four remaining muscles on the front of the thigh. It is the great Extensor muscle of the leg, forming a large fleshy mass which covers the front and sides of the femur, being united below into a single tendon, attached to the patella, and above subdivided into separate portions, which have received distinct names. Of these, one occupying the middle of the thigh, connected above with the ilium, is called the **Rectus femoris**, from its straight course. The other divisions lie in immediate connection with the shaft of the femur, which they cover from the trochanters to the condyles. The portion on the outer side of the femur is termed the **Vastus externus**; that covering the inner side, the **Vastus internus**; and that covering the front of the femur, the **Crureus**. The two latter portions are, however, so intimately blended as to form but one muscle.

The **Rectus femoris** is situated in the middle of the anterior region of the thigh: it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: one the straight tendon, or short head, from the anterior inferior spinous process of the ilium; the other is flattened, and curves outward, to be attached to a groove above the brim of the acetabulum; this is the reflected tendon, or long head, of the Rectus; it unites with the straight tendon at an acute angle, and then spreads into an aponeurosis, from which the muscular fibres arise. The muscle terminates in a broad and thick aponeurosis which occupies the lower two-thirds of its posterior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the patella in common with the Vasti and Crureus.

**Relations.**—By its superficial surface, with the anterior fibres of the Gluteus minimus, the Tensor vaginæ femoris, the Sartorius, and the Psoas and Iliacus; by its lower three-fourths, with the fascia lata; by its posterior surface, with the hip-joint, the external circumflex vessels, and the Crureus and Vasti muscles.

The three remaining muscles have been described collectively by some anatomists, separate from the Rectus, under the name of the **Triceps extensor cruris**.

The **Vastus externus** is the largest part of the Quadriceps extensor. It arises by a broad aponeurosis, which is attached to the tubercle of the femur, to the anterior and inferior borders of the great trochanter, to a rough line leading from the trochanter major to the linea aspera, and to the outer lip of the linea aspera: this aponeurosis covers the upper three-fourths of the muscle, and from its inner surface many fibres arise. A few additional fibres arise from the tendon of the Gluteus maximus and from the external intermuscular septum between the Vastus externus and short head of the Biceps. The fibres form a large fleshy mass which is attached to a strong aponeurosis, placed on the under surface of the muscle at its lower part: this becomes contracted and thickened into a flat tendon, which is inserted into the outer border of the patella, blending with the great extensor tendon.

---

1 Mr. W. R. Williams, in an interesting paper in the *Journ. of Anat. and Phys.*, vol. xiii. p. 204, points out that the reflected tendon is the real origin of the muscle, and is alone present in early fetal life. The direct tendon is merely an accessory band of condensed fascia. The paper will well repay perusal, though in some particulars I think the description in the text more generally accurate.—Ed.
Relations.—By its superficial surface, with the Rectus, the Tensor vaginæ femoris, the fascia lata, and the Gluteus maximus, from which it is separated by a synovial bursa; by its deep surface, with the Crureus, some large branches of the external circumflex artery and anterior crural nerve being interposed.

The Vastus internus and Crureus are so inseparably connected together as to form but one muscle, as which it will be accordingly described. It is the smallest portion of the Quadriceps extensor. The anterior portion of it, covered by the Rectus, is called the Crureus; the internal portion, which lies immediately beneath the fascia lata, the Vastus internus. It arises by an aponeurosis, which is attached to the lower part of the line that extends from the inner side of the neck of the femur to the linea aspera, from the inner lip of the linea aspera, from the ridge leading from the linea aspera to the internal condyle and internal intermuscular septum. It also arises from nearly the whole of the internal, anterior, and external surfaces of the shaft of the femur, limited, above, by the line between the two trochanters, and extending, below, to within the lower fourth of the bone. From these different origins the fibres converge to a broad aponeurosis which covers the anterior surface of the middle portion of the muscle (the Crureus) and the deep surface of the inner division of the muscle (the Vastus internus), and which gradually narrows down to its insertion into the patella, where it blends with the other portions of the Quadriceps extensor. The muscular fibres of the Vastus internus extend lower down than those of the Vastus externus, so that the capsule of the joint is less covered with muscular fibres on the outer than on the inner side.

Relations.—By its superficial surface, with the Psoas and Iliacus, the Rectus, Sartorius, Pectineus, Adductors, and fascia lata, femoral vessels, and saphenous nerve; by its deep surface, with the femur, Subcrureus, and synovial membrane of the knee-joint.

The student will observe the striking analogy that exists between the Quadriceps extensor and the Triceps muscle in the upper extremity. So close is this similarity that M. Cruveilhier has described it under the name of the Triceps femoralis. Like the Triceps extensor cubiti, it consists of three distinct divisions, or heads: a middle or long head, the Rectus, analogous to the long head of the Triceps, attached to the ilium, and two other portions, which may be called the external and internal heads of the Triceps femoralis. These, it will be noticed, are strictly analogous to the outer and inner heads of the Triceps in the arm.

The tendons of the different portions of the Quadriceps extensor unite at the lower part of the thigh, so as to form a single strong tendon which is inserted into the upper part of the patella. More properly, the patella may be regarded as a sesamoid bone, developed in the tendon of the Quadriceps, and the ligamentum patellae, which is continued from the lower part of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle. A synovial bursa, the post-patellar bursa, is interposed between the tendon and the upper part of the tuberosity of the tibia; and another, the prepatellar bursa, is placed over the patella itself. This latter bursa often becomes enlarged, constituting "housemaid's knee."

The Subcrureus is a small muscle, usually distinct from the Crureus, but occasionally blended with it, which arises from the anterior surface of the lower part of the shaft of the femur, and is inserted into the upper part of the cul-de-sac of the capsular ligament which projects upward beneath the Quadriceps for a variable distance. It sometimes consists of two separate muscular bundles.

Nerves.—The Tensor vaginæ femoris is supplied by the superior gluteal nerve; the other muscles of this region by branches from the anterior crural.

Actions.—The Tensor vaginæ femoris is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct and to rotate the thigh inward. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur, and by means of the ilio-tibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the
Gluteus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next rotates the thigh outward. It was formerly supposed to adduct the thigh, so as to cross one leg over the other, and hence received its name of Sartorius, or tailor's muscle (sartor, a tailor), because it was supposed to assist in crossing the legs in the squatting position. When the knee is bent the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inward. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists in rotating the pelvis. The Quadriceps extensor extends the leg upon the thigh. Taking its fixed point from the leg, as in standing, this muscle will act upon the femur, supporting it perpendicularly upon the head of the tibia, and thus maintaining the entire weight of the body, or in the stooping position it will straighten the knee, and therefore assist the trunk in rising into the erect position. The Rectus muscle assists the Psoas and Iliacus in supporting the pelvis and trunk upon the femur or in bending it forward.

Surgical Anatomy.—A few fibres of the Rectus muscle are liable to be ruptured from severe strain. This accident is especially liable to occur during the games of football and cricket, and is sometimes known as "cricket thigh." The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus muscle stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps extensor may be torn away from its insertion into the patella, or the tendon of the patella may be ruptured about an inch above the bone. This accident is caused in the same manner as fracture of the patella by muscular action is produced—viz. by a violent muscular effort to prevent falling whilst the knee is in a position of semiflexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place.

Internal Femoral Region.

Gracilis.

Pectineus.

Adductor magnus.

Adductor longus.

Adductor brevis.

Gracilis (Figs. 326, 329) is the most superficial muscle on the inner side of the thigh. It is thin and flattened, broad above, narrow and tapering below. It arises by a thin aponeurosis, between two and three inches in breadth, from the lower half of the margin of the synphysis and the inner margin of the descending ramus of the os pubis. The fibres pass vertically downward, and terminate in a rounded tendon which passes behind the internal condyle of the femur, and, curving round the inner tuberosity of the tibia, becomes flattened, and is inserted into the upper part of the inner surface of the shaft of the tibia, below the tuberosity. The tendon of this muscle is situated immediately above that of the Semitendinosus, and is surrounded by the tendon of the Sartorius, with which it is in part blended. As it passes across the internal lateral ligament of the knee-joint it is separated from it by a synovial bursa common to it and the Semitendinosus muscle.

Relations.—By its superficial surface, with the fascia lata and the Sartorius below: the internal saphenous vein crosses it obliquely near its lower part, lying superficial to the fascia lata; the internal saphenous nerve emerges between its tendon and that of the Sartorius; by its deep surface, with the Adductor brevis and the Adductor magnus and the internal lateral ligament of the knee-joint.

The Pectineus (Fig. 326) is a flat, quadrangular muscle situated at the anterior part of the upper and inner aspect of the thigh. It arises from the linea ilipectinea, from the surface of the bone in front of it between the pectineal eminence and spine of the os pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downward, backward, and outward, to be inserted into a rough line leading from the lesser trochanter to the linea aspera.

Relations.—By its anterior surface, with the pubic portion of the fascia lata.
which separates it from the femoral vessels and internal saphenous vein; by its posterior surface, with the capsular ligament of the hip-joint, the Adductor brevis and Obturator externus muscles, the obturator vessels and nerve being interposed; by its outer border, with the Psoas, a cellular interval separating them, through which passes the internal circumflex vessels; by its inner border, with the margin of the Adductor longus.

The Adductor longus, the most superficial of the three Adductors, is a flat triangular muscle lying on the same plane as the Pectineus. It arises, by a flat narrow tendon, from the front of the os pubis, at the angle of junction of the crest with the symphysis; and soon expands into a broad fleshy belly, which, passing downward, backward, and outward, is inserted, by an aponeurosis, into the linea aspera, between the Vastus internus and the Adductor magnus, with which it is usually blended.

Relations.—By its anterior surface, with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; by its posterior surface, with the Adductor brevis and magnus, the anterior branches of the obturator nerve, and with the profunda artery and vein near its insertion; by its outer border, with the Pectineus; by its inner border, with the Gracilis.

The Pectineus and Adductor longus should now be divided near their origin, and turned downward, when the Adductor brevis and Obturator externus will be exposed.

The Adductor brevis is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the body and descending ramus of the os pubis, between the Gracilis and Obturator externus. Its fibres, passing backward, outward, and downward, are inserted, by an aponeurosis, into the lower part of the line leading from the lesser trochanter to the linea aspera and the upper part of the linea aspera, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—By its anterior surface, with the Pectineus, Adductor longus, profunda femoris artery, and anterior branches of the obturator nerve; by its posterior surface, with the Adductor magnus and posterior branch of the obturator nerve; by its outer border, with the Obturator externus and conjoined tendon of the Psoas and Iliacus; by its inner border, with the Gracilis and Adductor magnus.
This muscle is pierced, near its insertion, by the middle perforating branch of the profundus femoris artery.

The Adductor brevis should now be cut away near its origin, and turned outward, when the entire extent of the Adductor magnus will be exposed.

The Adductor magnus is a large triangular muscle forming a septum between the muscles on the inner and those on the back of the thigh. It arises from a small part of the descending ramus of the os pubis, from the ascending ramus of the ischium, and from the outer margin and under surface of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are very short, horizontal in direction, and are inserted into the rough line leading from the great trochanter to the linea aspera, internal to the Gluteus maximus; those from the ramus of the ischium are directed downward and outward with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the linea aspera and the upper part of its internal prolongation below. The internal portion of the muscle, consisting principally of those fibres which arise from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and terminate about the lower third of the thigh in a rounded tendon, which is inserted into the Adductor tubercle on the inner condyle of the femur, being connected by a fibrous expansion to the line leading upward from the tubercle to the linea aspera. Between the two portions of the muscle an interval is left, tendinous in front, fleshy behind, for the passage of the femoral vessels into the popliteal space. The external portion of the muscle at its attachment to the femur presents three or four osseo-aponeurotic openings, formed by tendinous arches attached to the bone, from which muscular fibres arise. The three superior of these apertures are for the three perforating arteries, and the fourth, when it exists, for the terminal branch of the profunda.

Relations.—By its anterior surface, with the Pectineus, Adductor brevis, Adductor longus, and the femoral and profunda vessels and obturator nerve; by its posterior surface, with the great sciatic nerve, the Gluteus maximus, Biceps, Semitendinosus, and Semimembranosus. By its superior or shortest border it lies parallel with the Quadratus femoris, the internal circumflex artery passing between them; by its internal or longest border, with the Gracilis, Sartorius, and fascia lata; by its external or attached border it is inserted into the femur behind the Adductor brevis and Adductor longus, which separate it from the Vastus internus, and in front of the Gluteus maximus and short head of the Biceps, which separate it from the Vastus externus.

Nerves.—All the muscles of this group are supplied by the obturator nerve. The Pectineus receives additional branches from the accessory obturator and anterior crural, and the Adductor magnus an additional branch from the great sciatic.

Actions.—The Pectineus and three Adductors abduct the thigh powerfully; they are especially used in horse exercise, the flanks of the horse being grasped between the knees by the actions of these muscles. In consequence of the obliquity of their insertion into the linea aspera they rotate the thigh outward, assisting the external Rotators, and when the limb has been abducted they draw it inward, carrying the thigh across that of the opposite side. The Pectineus and Adductor brevis and longus assist the Psoas and Iliacus in flexing the thigh upon the pelvis. In progression, also, all these muscles assist in drawing forward the hinder limb. The Gracilis assists the Sartorius in flexing the leg and rotating it inward; it is also an adductor of the thigh. If the lower extremities are fixed, these muscles may take their fixed point from below and act upon the pelvis, serving to maintain the body in an erect posture, or, if their action is continued, to flex the pelvis forward upon the femur.

Surgical Anatomy.—The Adductor longus is liable to be severely strained in those who ride much on horseback, or its tendon to be ruptured by suddenly gripping the saddle. And, occasionally, especially in cavalry soldiers, the tendon may become ossified, constituting the "rider's bone."
THE MUSCLES AND FASCIEÆ.

THE HIP.

Gluteal Region.

Gluteus maximus.
Gluteus medius.
Gluteus minimus.
Pyriformis.

Quadrate femoris.

Dissection (Fig. 328).—The subject should be turned on its face, a block placed beneath the pelvis to make the buttocks tense, and the limbs allowed to hang over the end of the table, with the foot inverted and the thigh abducted. Make an incision through the integument along the crest of the ilium to the middle of the sacrum, and thence downward to the tip of the coccyx, and carry a second incision from that point obliquely downward and outward to the outer side of the thigh, four inches below the great trochanter. The portion of integument included between these incisions is to be removed in the direction shown in the figure.

The Gluteus maximus (Fig. 329), the most superficial muscle in the gluteal region, is a very broad and thick, fleshy mass of a quadrilateral shape, which forms the prominence of the nates. Its large size is one of the most characteristic points in the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. In structure the muscle is remarkably coarse, being made up of muscular fasciculi lying parallel with one another, and collected together into large bundles, separated by deep cellular intervals. It arises from the superior gluteal line of the ilium and the portion of bone, including the crest, immediately behind it; from the posterior surface of the lower part of the sacrum, the side of the coccyx, the aponeurosis of the Erector spine muscle, and the great sacro-scatic ligament. The fibres are directed obliquely downward and outward; those forming the upper together with the superficial fibres of the lower portion terminate in a thick tendinous lamina, which passes across the great trochanter, and is inserted into the fascia lata covering the outer side of the thigh, the deep fibres of the lower portion being inserted by a tendon into the rough line leading from the great trochanter to the linea aspera between the Vastus externus and Adductor magnus.

Three synovial bursæ are usually found in relation with this muscle. One of these, of large size, and generally multilocular, separates it from the great trochanter. A second, often wanting, is situated on the tuberosity of the ischium. A third is found between the tendon of this muscle and the Vastus externus.

Relations.—By its superficial surface, with a thin fascia, which separates it from the subcutaneous tissue; by its deep surface, from above downward, with the ilium, sacrum, coccyx, and great sacro-scatic ligament, part of the Gluteus medius, Pyriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, great trochanter, the origin of the Biceps, Semitendinosus, Semimembranosus, and Adductor magnus muscles. The gluteal vessels and superior gluteal nerve are seen issuing from the pelvis above the Pyriformis muscle, the sciatic and

Fig. 328.—Dissection of lower extremity. Posterior view.
internal pudic vessels and nerves, and muscular branches from the sacral plexus below it. Its upper border is connected with the Gluteus medius by the fascia lata; its lower border is free and prominent.

Dissection.—Now divide the Gluteus maximus near its origin by a vertical incision carried from its upper to its lower border; a cellular interval will be exposed, separating it from the Gluteus medius and External rotator muscles beneath. The upper portion of the muscle is to be altogether detached, and the lower portion turned outward; the loose areolar tissue filling up the interspace between the trochanter major and tuberosity of the ischium being removed, the parts already enumerated as exposed by the removal of this muscle will be seen.

The Gluteus medius is a broad, thick, radiated muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Gluteus maximus; its anterior two-thirds by the fascia lata, which separates it from the integument. It arises from the outer surface of the ilium, between the superior and middle gluteal lines, and from the outer lip of that portion of the crest which is between them; it also arises from the dense fascia (Gluteal aponeurosis) covering its outer surface. The fibres converge to a strong flattened tendon which is inserted into the oblique line which traverses the outer surface of the great trochanter. A synovial bursa separates the tendon of the muscle from the surface of the trochanter in front of its insertion.

Relations.—By its superficial surface, with the Gluteus maximus behind, the Tensor vaginalis femoris and deep fascia in front; by its deep surface, with the Gluteus minimus and the gluteal vessels and superior gluteal nerve. Its anterior border is blended with the Gluteus minimus. Its posterior border lies parallel with the Pyriformis, the gluteal vessels intervening.
This muscle should now be divided near its insertion and turned upward, when the Gluteus minimus will be exposed.

The Gluteus minimus, the smallest of the three Glutei, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface of the ilium, between the middle and inferior gluteal lines, and behind, from the margin of the great sacro-sciatic notch; the fibres converge to the deep surface of a radiated aponeurosis, which, terminating in a tendon, is inserted into an impression on the anterior border of the great trochanter. A synovial bursa is interposed between the tendon and the great trochanter.

**Relations.**—By its superficial surface, with the Gluteus medius, and the gluteal vessels and superior gluteal nerve; by its deep surface, with the ilium, the reflected tendon of the Rectus femoris, and capsular ligament of the hip-joint. Its anterior margin is blended with the Gluteus medius; its posterior margin is often joined with the tendon of the Pyriformis.

The Pyriformis is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the Gluteus medius. It is situated partly within the pelvis at its posterior part and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and also from the groove leading from the foramina: a few fibres also arise from the margin of the great sacro-sciatic foramen and from the anterior surface of the great sacro-sciatic ligament. The muscle passes out of the pelvis through the great sacro-sciatic foramen, the upper part of which it fills, and is inserted by a rounded tendon into the upper border of the great trochanter, behind, but often blended with, the tendon of the Obturator internus and Gemelli muscles.

**Relations.**—By its anterior surface, within the pelvis, with the Rectum (especially on the left side), the sacral plexus of nerves, and the branches of the internal iliac vessels; external to the pelvis, with the os innominatum and capsular ligament of the hip-joint; by its posterior surface, within the pelvis, with the sacrum, and external to it, with the Gluteus maximus; by its upper border, with the Gluteus medius, from which it is separated by the gluteal vessels and superior gluteal nerve; by its lower border, with the Gemellus superior and Coccygeus, the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus, passing from the pelvis in the interval between the two muscles.

The Obturator membrane is a thin layer of interlacing fibres which closes the obturator foramen. It is attached, externally, to the margin of the foramen; internally, to the posterior surface of the ischio-pubic ramus, internal to the inner margin of the foramen. It is occasionally incomplete, and presents at its upper and outer part a small canal, which is bounded below by a thickened band of fibres, for the passage of the obturator vessels and nerve. Each obturator muscle is connected with this membrane.

**Dissection.**—The next muscle, as well as the origin of the Pyriformis, can only be seen when the pelvis is divided and the viscera removed.

The Obturator internus, like the preceding muscle, is situated partly within the cavity of the pelvis and partly at the back of the hip-joint. It arises from the inner surface of the anterior and external wall of the pelvis, around the inner side of the obturator foramen, being attached to the descending ramus of the os pubis and the ascending ramus of the ischium, and at the side to the inner surface of the body of the ischium, between the margin of the obturator foramen in front and the great sacro-sciatic notch behind, and to the inner surface of the ilium below the brim of the true pelvis. It also arises from the inner surface of the obturator membrane, except at its lower part, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve. The fibres are directed backward and downward, and terminate in four or five tendinous bands which are found on its deep surface: these bands are reflected at a right
angle over the inner surface of the tuberosity of the ischium, which is grooved for their reception: the groove is covered with cartilage and lined with a synovial bursa. The muscle leaves the pelvis by the lesser sacro-sciatic notch, and the tendinous bands unite into a single flattened tendon, which passes horizontally outward, and, after receiving the attachment of the Gemelli, is inserted into the inner surface of the great trochanter in front of the Obturator externus. A synovial bursa, narrow and elongated in form, is usually found between the tendon of this muscle and the capsular ligament of the hip: it occasionally communicates with the bursa between the tendon and the tuberosity of the ischium, the two forming a single sac.

In order to display the peculiar appearances presented by the tendon of this muscle, it must be divided near its insertion and reflected outward.

**Relations.**—*Within the pelvis* this muscle is in relation, by its *anterior surface*, with the obturator membrane and inner surface of the anterior wall of the pelvis; by its *posterior surface*, with the pelvic and obturator fasciae, which separate it from the Levator ani; and it is crossed by the internal pudic vessels and nerve. This surface forms the outer boundary of the ischio-rectal fossa. *External to the pelvis* it is covered by the great sciatic nerve and Gluteus maximus, and rests on the back part of the hip-joint.

The **Gemelli** are two small muscular fasciculi, accessories to the tendon of the Obturator internus, which is received into a groove between them. They are called *superior and inferior*.

The **Gemellus superior**, the smaller of the two, arises from the outer surface of the spine of the ischium, and, passing horizontally outward, becomes blended with the upper part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter. This muscle is sometimes wanting.

**Relations.**—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *deep surface*, with the capsule of the hip-joint; by its *upper border*, with the lower margin of the Pyriformis; by its *lower border*, with the tendon of the Obturator internus.

The **Gemellus inferior** arises from the upper part of the tuberosity of the ischium, where it forms the lower edge of the groove for the Obturator internus tendon, and, passing horizontally outward, is blended with the lower part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter.

**Relations.**—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *deep surface*, with the capsular ligament of the hip-joint; by its *upper border*, with the tendon of the Obturator internus; by its *lower border*, with the tendon of the Obturator externus and Quadratus femoris.

The **Quadratus femoris** is a short, flat muscle, quadrilateral in shape (hence its name), situated between the Gemellus inferior and the upper margin of the Adductor magnus. It arises from the external lip of the tuberosity of the ischium, and, proceeding horizontally outward, is inserted into the upper part of the linea quadrati; that is, the line which crosses the posterior intertrochanteric line. A synovial bursa is often found between the under surface of this muscle and the lesser trochanter, to which it extends.

**Relations.**—By its *posterior surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *anterior surface*, with the tendon of the Obturator externus and trochanter minor and with the capsule of the hip-joint; by its *upper border*, with the Gemellus inferior. Its *lower border* is separated from the Adductor magnus by the terminal branches of the internal circumflex vessels.

**Dissection.**—In order to expose the next muscle (the Obturator externus), it is necessary to remove the Psoas, Iliacus, Pectineus, and Adductor brevis and longus muscles from the front and inner side of the thigh, and the Gluteus maximus and Quadratus femoris from the back part. Its dissection should, consequently, be postponed until the muscles of the anterior and internal femoral regions have been explained.
THE MUSCLES AND FASCIAE.

The **Obturator externus** (Fig. 327) is a flat, triangular muscle which covers the outer surface of the anterior wall of the pelvis. It arises from the margin of bone which forms the inner boundary of the obturator foramen—viz. from the body and descending ramus of the os pubis and the ramus of the ischium; it also arises from the inner two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres converging pass backward, outward, and upward, and terminate in a tendon which runs under and across the back part of the hip-joint and is inserted into the digital fossa of the femur.

**Relations.**—By its **anterior surface**, with the **Psoas**, **Iliacus**, **Pectineus**, Adductor magnus, Adductor brevis, and Gracilis, and more externally, with the neck of the femur and capsule of the hip-joint; by its **posterior surface**, with the obturator membrane and Quadratus femoris.

**Nerves.**—The Gluteus maximus is supplied by the inferior gluteal nerve from the sacral plexus; the Gluteus medius and minimus, by the superior gluteal; the Pyriformis, Gemelli, Obturator internus, and Quadratus femoris, by branches from the sacral plexus; and the Obturator externus, by the obturator nerve.

**Actions.**—The Gluteus maximus, when it takes its fixed point from the pelvis, extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the whole trunk upon the head of the femur, which is especially obvious in standing on one leg. Its most powerful action is to cause the body to regain the erect position after stooping by drawing the pelvis backward, being assisted in this action by the Biceps, Semitendinosus, and Semimembranosus. The Gluteus maximus is a tensor of the fascia lata, and by its connection with the ilio-tibial band it steadies the femur on the articular surface of the tibia during standing, when the extensor muscles are relaxed. The lower part of the muscle also acts as an abductor and external rotator of the limb. The Gluteus medius and minimus abduct the thigh when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor vaginae femoris. Their anterior fibres, by drawing the great trochanter forward, rotate the thigh inward, in which action they are also assisted by the Tensor vaginae femoris. Their posterior fibres rotate the thigh outward. The remaining muscles are powerful rotators of the thigh outward. In the sitting posture, when the thigh is flexed upon the pelvis, their action as rotator ceases, and they become abductors, with the exception of the Obturator externus, which still rotates the femur outward. When the femur is fixed, the Pyriformis and Obturator muscles serve to draw the pelvis forward if it has been inclined backward, and assist in steadying it upon the head of the femur.

**Posterior Femoral Region.**

**Dissection** (Fig. 328).—Make a vertical incision along the middle of the thigh, from the lower fold of the nates to about three inches below the back of the knee-joint, and there connect it with a transverse incision carried from the inner to the outer side of the leg. Make a third incision transversely at the junction of the middle with the lower third of the thigh. The integument having been removed from the back of the knee and the boundaries of the popliteal space examined, the removal of the integument from the remaining part of the thigh should be continued, when the fascia and muscles of this region will be exposed.

The **Biceps** (*Biceps flexor cruris*) is a large muscle, of considerable length, situated on the posterior and outer aspect of the thigh (Fig. 329). It arises by two heads. One, the long head, arises from the lower and inner facet on the back part of the tuberosity of the ischium by a tendon common to it and the Semitendinosus. The femoral, or short head, arises from the outer lip of the linea aspera, between the Adductor magnus and Vastus externus, extending up almost as high as the insertion of the Gluteus maximus, and from the external supracondylar line to within two inches of the outer condyle; it also arises from the
external intermuscular septum. The fibres of the long head form a fusiform belly, which, passing obliquely downward and a little outward, terminates in an aponeurosis which covers the posterior surface of the muscle and receives the fibres of the short head: this aponeurosis becomes gradually contracted into a tendon, which is inserted into the outer side of the head of the fibula, and by a small slip into the lateral surface of the external tuberosity of the tibia. At its insertion the tendon divides into two portions, which embrace the long external lateral ligament of the knee-joint, a strong prolongation being sent forward to the outer tuberosity of the tibia, which gives off an expansion to the fascia of the leg. The tendon of this muscle forms the outer hamstring.

**Relations.**—By its superficial surface, with the Gluteus maximus above, with the fascia lata and integument in the rest of its extent; by its deep surface, with the Semimembranosus, Adductor magnus, and Vastus externus, the great sciatic nerve, and, near its insertion, with the external head of the Gastrocnemius, Plantaris, the superior external articular artery, and the external popliteal nerve.

The Semitendinosus, remarkable for the great length of its tendon, is situated at the posterior and inner aspect of the thigh. It arises from the lower and inner facet on the tuberosity of the ischium by a tendon common to it and the long head of the Biceps; it also arises from an aponeurosis which connects the adjacent surfaces of the two muscles to the extent of about three inches after their origin. It forms a fusiform muscle, which, passing downward and inward, terminates a little below the middle of the thigh in a long round tendon which lies along the inner side of the popliteal space, then curves around the inner tuberosity of the tibia, and is inserted into the upper part of the inner surface of the shaft of that bone nearly as far forward as its anterior border. This tendon is surrounded by the tendon of the Sartorius, and lies below that of the Gracilis, to which it is united. A tendinous intersection is usually observed about the middle of the muscle.

**Relations.**—By its superficial surface, with the Gluteus maximus and fascia lata; by its deep surface, with the Semimembranosus, Adductor magnus, inner head of the Gastrocnemius, and internal lateral ligament of the knee-joint.

The Semimembranosus, so called from the membranous expansion on its anterior and posterior surfaces, is situated at the back part and inner side of the thigh. It arises by a thick tendon from the upper and outer facet on the back part of the tuberosity of the ischium, above and to the outer side of the Biceps and Semitendinosus, and is inserted into the groove on the inner and back part of the inner tuberosity of the tibia, beneath the internal lateral ligament. The tendon of the muscle at its origin expands into an aponeurosis which covers the upper part of its anterior surface; from this aponeurosis muscular fibres arise, and converge to another aponeurosis, which covers the lower part of its posterior surface and contracts into the tendon of insertion. The tendon of the muscle at its insertion gives off two fibrous expansions; one of these, of considerable size, passes upward and outward to be inserted into the back part of the outer condyle of the femur, forming part of the posterior ligament of the knee-joint. The second is continued downward to the fascia which covers the Popliteus muscle. The tendon also sends a few fibres to join the internal lateral ligament of the joint.

The tendons of the two preceding muscles, with that of the Gracilis, form the inner hamstring.

**Relations.**—By its superficial surface, with the Semitendinosus, Biceps, and fascia lata; by its deep surface, with the popliteal vessels, Adductor magnus, and inner head of the Gastrocnemius, from which it is separated by a synovial bursa; by its inner border, with the Gracilis; by its outer border, with the great sciatic nerve and its internal popliteal branch.

**Nerves.**—The muscles of this region are supplied by the great sciatic nerve.

**Actions.**—The hamstring muscles flex the leg upon the thigh. When the
knee is semiflexed, the Biceps, in consequence of its oblique direction downward and outward, rotates the leg slightly outward; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inward, assisting the Popliteus. Taking their fixed point from below, these muscles serve to support the pelvis upon the head of the femur and to draw the trunk directly backward, as in feats of strength, when the body is thrown backward in the form of an arch.

Surgical Anatomy.—The tendons of these muscles occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the Flexor muscles, or from stiffening of the ligamentous and other tissues surrounding the joint, the result of disease. This is effected by putting the tendon upon the stretch, and inserting a narrow, sharp-pointed knife between it and the skin; the cutting edge being then turned toward the tendon, it should be divided, taking great care that the wound in the skin is not at the same time enlarged. The relation of the external popliteal nerve to the tendon of the Biceps must always be borne in mind in dividing this tendon.

THE LEG.

Dissection (Fig. 325).—The knee should be bent, a block placed beneath it, and the foot kept in an extended position; then make an incision through the integument in the middle line of the leg to the ankle, and continue it along the dorsum of the foot to the toes. Make a second incision transversely across the ankle, and a third in the same direction across the bases of the toes; remove the flaps of integument included between these incisions in order to examine the deep fascia of the leg.

The Deep fascia of the Leg forms a complete investment to the muscles, but is not continued over the subcutaneous surfaces of the bones. It is continuous above with the fascia lata, receiving an expansion from the tendon of the Biceps on the outer side, and from the tendons of the Sartorius, Gracilis, and Semitendinosus on the inner side; in front it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and external malleolus of the fibula; below it is continuous with the annular ligaments of the ankle. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anticus and Extensor longus digitorum muscles, but thinner behind, where it covers the Gastrocnemius and Soleus muscles. Over the popliteal space it is much strengthened by transverse fibres which stretch across from the inner to the outer hamstring muscles, and it is here perforated by the external saphenous vein. Its deep surface gives off, on the outer side of the leg, two strong intermuscular septa which enclose the Peronei muscles, and separate them from the muscles on the anterior and posterior tibial regions and several smaller and more slender processes which enclose the indi-
vidual muscles in each region; at the same time a broad transverse intermuscular septum, called the deep transverse fascia of the leg, intervenes between the superficial and deep muscles in the posterior tibio-fibular region.

Now remove the fascia by dividing it in the same direction as the integument, excepting opposite the ankle, where it should be left entire. Commence the removal of the fascia from below, opposite the tendons, and detach it in the line of direction of the muscular fibres.

**Muscles of the Leg.**—These may be subdivided into three groups: those on the anterior, those on the posterior, and those on the outer side.

**Anterior Tibio-fibular Region.**

**Tibialis anticus.**

**Extensor proprius hallucis.**

**Extensor longus digitorum.**

**Peroneus tertius.**

The **Tibialis anticus** is situated on the outer side of the tibia; it is thick and fleshy at its upper part, tendinous below. It arises from the outer tuberosity and upper two-thirds of the external surface of the shaft of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septum between it and the Extensor longus digitorum: the fibres pass vertically downward, and terminate in a tendon which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the innermost compartment of the anterior annular ligament, it is inserted into the inner and under surface of the internal cuneiform bone and base of the metatarsal bone of the great toe.

**Relations.**—By its anterior surface, with the fascia and with the annular ligament; by its posterior surface, with the interosseous membrane, tibia, ankle-joint, and inner side of the tarsus: this surface also overlaps the anterior tibial vessels and nerve in the upper part of the leg. By its inner surface, with the tibia; by its outer surface, with the Extensor longus digitorum and Extensor proprius hallucis, and the anterior tibial vessels and nerve.

The **Extensor proprius hallucis** is a thin, elongated, and flattened muscle situated between the Tibialis anticus and Extensor longus digitorum. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, its origin being internal to that of the Extensor longus digitorum; it also arises from the interosseous membrane to a similar extent. The fibres pass downward, and terminate in a tendon which occupies the anterior border of the muscle, passes through a distinct compartment in the horizontal portion of the annular ligament, crosses the anterior tibial vessels near the bend of the ankle, and is inserted into the base of the last phalanx of the great toe. Opposite the metatarso-phalangeal articulation the tendon gives off a thin prolongation on each side, which covers the surface of the joint. It usually sends an expansion from the inner side of the tendon, to be inserted into the base of the first phalanx.

**Relations.**—By its anterior surface, with the fascia and the anterior annular ligament; by its posterior surface, with the interosseous membrane, fibula, tibia, ankle-joint, and Extensor brevis digitorum; by its outer side, with the Extensor longus digitorum above, the dorsalis pedis vessels and anterior tibial nerve below; by its inner side, with the Tibialis anticus and the anterior tibial vessels above.

The **Extensor longus digitorum** is an elongated, flattened, semipenniform muscle situated the most externally of all the muscles on the fore part of the leg. It arises from the outer tuberosity of the tibia; from the upper three-fourths of the anterior surface of the shaft of the fibula; from the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anticus on the inner and the Peronei on the outer side. The tendon enters a canal in the annular ligament with the Peroneus tertius, and divides into four slips, which run across the dorsum of the foot and are inserted into the second and third phalanges of the four lesser toes. The mode in which the tendons are inserted is the following: The three inner tendons opposite the metatarso-phalangeal articulation are joined, on their outer side, by a tendon of the Extensor...
brevis digitorum. They all receive a fibrous expansion from the Interossei and Lumbricales, and then spread out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: this aponeurosis, at the articulation of the first with the second phalanx, divides into three slips—a middle one, which is inserted into the base of the second phalanx, and two lateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onward, to be inserted into the base of the third.

**Relations.**—By its anterior surface, with the fascia and the annular ligament; by its posterior surface, with the fibula, interosseous membrane, ankle-joint, and Extensor brevis digitorum; by its inner side, with the Tibialis anticus, Extensor proprius hallucis, and anterior tibial vessels and nerve; by its outer side, with the Peroneus longus and brevis.

The Peroneus tertius is a part of the Extensor longus digitorum, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower fourth of the anterior surface of the fibula, from the lower part of the interosseous membrane, and from an intermuscular septum between it and the Peroneus brevis. The tendon, after passing through the same canal as the Extensor longus digitorum, is inserted into the dorsal surface of the base of the metatarsal bone of the little toe, on its inner side. This muscle is sometimes wanting.

**Nerves.**—These muscles are supplied by the anterior tibial nerve.

**Actions.**—The Tibialis anticus and Peroneus tertius are the flexors of the tarsus upon the leg; the former muscle, from the obliquity in the direction of its tendon, raises the inner border of the foot; and the latter, acting with the Peroneus brevis and longus, draws the outer border of the foot upward and the sole outward. The Extensor longus digitorum and Extensor proprius hallucis extend the phalanges of the toes, the action being the same as that of the corresponding muscles of the hand, and flex the tarsus. Taking their fixed point from below in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position.

**Posterior Tibio-fibular Region.**

**Dissection (Fig. 328).**—Make a vertical incision along the middle line of the back of the leg, from the lower part of the popliteal space to the heel, connecting it below by a transverse incision extending between the two malleoli; the flaps of integument being removed, the fascia and muscles should be examined.

The muscles in this region of the leg are subdivided into two layers—superficial and deep. The superficial layer constitutes a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct connection with his ordinary attitude and mode of progression.

**Superficial Layer.**

Gastrocnemius.  
Soleus.  
Plantaris.

The Gastrocnemius is the most superficial muscle, and forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by two strong flat tendons. The inner head, the larger and a little the more posterior, arises from a depression at the upper and back part of the inner condyle. The outer head arises from the upper and back part of the external condyle, immediately above the origin of the Popliteus. Both heads, also, arise by a few tendinous and fleshy fibres from the ridges which are continued upward from the condyles to the linea aspersa. Each tendon spreads out into an aponeurosis which covers the posterior surface of that portion of the muscle to which it belongs, that covering the inner head being longer and thicker than the outer. From the anterior surface of these tendinous expansions muscular fibres are given off. The fibres in the median line, which correspond to the
accessory portions of the muscle derived from the bifurcations of the linea aspera, unite at an angle upon a median tendinous raphe below: the remaining fibres converge to the posterior surface of an aponeurosis which covers the anterior surface of the muscle, and this, gradually contracting, unites with the tendon of the Soleus, and forms with it the tendo Achillis.

 Relations.—By its superficial surface, with the fascia of the leg, which separates it from the external saphenous vein and nerve; by its deep surface, with the posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and internal popliteal nerve. The tendon of the inner head corresponds with the back part of the inner condyle, from which it is separated by a synovial bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the outer head contains a sesamoid fibro-cartilage (rarely osseous) where it plays over the corresponding outer condyle; and one is occasionally found in the tendon of the inner head.

The Gastrocnemius should be divided across, just below its origin, and turned downward, in order to expose the next muscles.

The Soleus is a broad flat muscle situated immediately beneath the Gastrocnemius. It has received its name from its resemblance in shape to a sole-fish. It arises by tendinous fibres from the back part of the head of the fibula and from the upper third of the posterior surface of its shaft; from the oblique line of the tibia and from the middle third of its internal border; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, beneath which the posterior tibial vessels and nerve pass. The fibres pass backward to an aponeurosis which covers the posterior surface of the muscle, and this, gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo Achillis.

 Relations.—By its superficial surface, with the Gastrocnemius and Plantaris; by its deep surface, with the Flexor longus digitorum, Flexor longus hallucis, Tibialis posticus, and posterior tibial vessels and nerve, from which it is separated by the transverse intermuscular septum or deep transverse fascia of the leg.

The Tendo Achillis, the common tendon of the Gastrocnemius and Soleus, is the thickest and strongest tendon in the body. It is about six inches in length, and commences about the middle of the leg, but receives fleshy fibres on its anterior surface nearly to its lower end. Gradually becoming contracted below, it is inserted into the lower part of the posterior surface of the os calcis, a synovial

---

**Fig. 331.**—Muscles of the back of the leg. Superficial layer.
bursa being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is usually about an inch and a half above its insertion. The tendon is covered by the fascia and the integument, and is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissue. Along its outer side, but superficial to it, is the external saphenous vein.

The Plantaris is an extremely diminutive muscle placed between the Gastrocnemius and Soleus, and remarkable for its long and delicate tendon. It arises from the lower part of the outer prolongation of the linea aspera and from the posterior ligament of the knee-joint. It forms a small fusiform belly, about three or four inches in length, terminating in a long slender tendon which crosses obliquely between the two muscles of the calf, and, running along the inner border of the tendo Achillis, is inserted with it into the posterior part of the os calcis. This muscle is occasionally double, and is sometimes wanting. Occasionally, its tendon is lost in the internal annular ligament or in the fascia of the leg.

Nerves.—These muscles are supplied by the internal popliteal nerve, the Soleus receiving an additional branch from the posterior tibial nerve.

Actions.—The muscles of the calf are constantly called into use in standing, walking, dancing, and leaping. In walking these muscles draw powerfully upon the os calcis, raising the heel, and with it the entire body, from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forward. In standing, the Soleus, taking its fixed point from below, steadies the leg upon the foot, and prevents the body from falling forward, to which there is a constant tendency from the superincumbent weight. The Gastrocnemius, acting from below, serves to flex the femur upon the tibia, assisted by the Popliteus. The Plantaris is the rudiment of a large muscle which exists in some of the lower animals and serves as a tensor of the plantar fascia. In man it is merely an accessory to the Gastrocnemius, extending the ankle if the foot is free or bending the knee if the foot is fixed.

Deep Layer.

Popliteus. Flexor longus digitorum.
Flexor longus hallucis. Tibialis posterior.

Dissection.—Detach the Soleus from its attachment to the fibula and tibia, and turn it downward, when the deep layer of muscles is exposed, covered by the deep transverse fascia of the leg.

The Deep Transverse Fascia of the leg is a broad, transverse, intermuscular septum interposed between the superficial and deep muscles in the posterior tibio-fibular region. On either side it is connected to the margins of the tibia and fibula. Above, where it covers the Popliteus, it is thick and dense, and receives an expansion from the tendon of the Semimembranosus; it is thinner in the middle of the leg, but below, where it covers the tendons passing behind the malleoli, it is thickened. It is continued onward in the interval between the ankle and the heel, where it covers the vessels and is blended with the internal annular ligament.

This fascia should now be removed, commencing from below opposite the tendons, and detaching it from the muscles in the direction of their fibres.

The Popliteus is a thin, flat, triangular muscle, which forms part of the floor of the popliteal space, and is covered by a tendinous expansion derived from the Semimembranosus muscle. It arises by a strong tendon, about an inch in length, from a deep depression on the outer side of the external condyle of the femur, and from the posterior ligament of the knee-joint, and is inserted into the inner two-thirds of the triangular surface above the oblique line on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the surface of the muscle. The tendon of the muscle is covered by that of the Biceps and the external lateral ligament of the knee-joint; it grooves the outer border of the
external semilunar fibro-cartilage, and is invested by the synovial membrane of the knee-joint.

Relations.—By its superficial surface, with the fascia above mentioned, which separates it from the Gastrocnemius, Plantaris, popliteal vessels, and internal popliteal nerve; by its deep surface, with the superior tibio-fibular articulation and back of the tibia.

The Flexor longus hallucis is situated on the fibular side of the leg. It arises from the lower two-thirds of the posterior surface of the shaft of the fibula, with the exception of an inch at its lowest part; from the lower part of the interosseus membrane; from an intermuscular septum between it and the Peronei, externally; and from the fascia covering the Tibialis posticus, which is attached to the inner border of the fibula externally and to the posterior surface of the tibia between the origins of the Tibialis posticus and the Flexor longus digitorum, internally. The fibres pass obliquely downward and backward, and terminate round a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon passes through a groove on the posterior surface of the lower end of the tibia; it then passes through another groove on the posterior surface of the astragalus, and along a third groove, beneath the sustentaculum tali of the os calcis, into the sole of the foot, where it runs forward between the two heads of the Flexor brevis hallucis, and is inserted into the base of the last phalanx of the great toe. The grooves in the astragalus and os calcis, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals lined by synovial membrane; and as the tendon crosses the sole of the foot, it is connected to the common flexor by a tendinous slip.

Relations.—By its superficial surface, with the Soleus and tendo Achillis, from which it is separated by the deep transverse fascia; by its deep surface, with the fibula, Tibialis posticus, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; by its outer border, with the Peronei; by its inner border, with the Tibialis posticus and posterior tibial vessels and nerve.

The Flexor longus digitorum (perforans) is situated on the tibial side of the leg. At its origin it is thin and pointed, but gradually increases in size as it descends. It arises from the posterior surface of the shaft of the tibia, immediately below the oblique line, to within three inches of its extremity internal to the tibial origin of the Tibialis posticus; some fibres also arise from the fascia covering the Tibialis posticus. The fibres terminate in a tendon which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the internal malleolus in a groove common to it and the Tibialis posticus, but separated from the latter by a fibrous septum, each tendon being contained in a special sheath lined by a separate synovial
membrane. It then passes obliquely forward and outward, crossing over the internal lateral ligament into the sole of the foot (Fig. 334), where, crossing superficially to the tendon of the Flexor longus hallucis, to which it is connected by a strong tendinous slip, it becomes expanded, is joined by the Flexor accessorius, and finally divides into four tendons which are inserted into the bases of the last phalanges of the four lesser toes, each tendon passing through a fissure in the tendon of the Flexor brevis digitorum opposite the base of the first phalanges.

Relations.—In the leg: by its superficial surface, with the posterior tibial vessels and nerve, and the deep transverse fascia, which separates it from the Soleus muscle; by its deep surface, with the Tibia and Tibialis posticus. In the foot it is covered by the Abductor hallucis and Flexor brevis digitorum, and crosses superficial to the Flexor longus hallucis.

The Tibialis posticus lies between the two preceding muscles, and is the most deeply seated of all the muscles in the leg. It commences above by two pointed processes, separated by an angular interval, through which the anterior tibial vessels pass forward to the front of the leg. It arises from the whole of the posterior surface of the interosseous membrane, excepting its lowest part, from the posterior surface of the shaft of the tibia, external to the Flexor longus digitorum, between the commencement of the oblique line above, and the middle of the external border of the bone below, and from the upper two-thirds of the internal surface of the fibula; some fibres also arise from the deep transverse fascia and from the intermuscular septa, separating it from the adjacent muscles on each side. This muscle, in the lower fourth of the leg, passes in front of the Flexor longus digitorum, and terminates in a tendon which passes through a groove behind the inner malleolus with the tendon of that muscle, but enclosed in a separate sheath; it then passes through another sheath, over the internal lateral ligament into the foot, and then beneath the inferior calcaneo-navicular ligament, and is inserted into the tuberosity of the navicular and internal cuneiform bones. The tendon of this muscle contains a sesamoid fibro-cartilage as it passes over the navicular bone, and gives off fibrous expansions, one of which passes backward to the sustentaculum tali of the os calcis, others outward to the middle and external cuneiform and cuboid, and some forward to the bases of the second, third, and fourth metatarsal bones (Fig. 335).

Relations.—By its superficial surface, with the Soleus, from which it is separated by the deep transverse fascia, the Flexor longus digitorum, the posterior tibial vessels and nerve, and the peroneal vessels; by its deep surface, with the interosseous ligament, the tibia, fibula, and ankle-joint.

Nerves.—The Popliteus is supplied by the internal popliteal nerve, the remaining muscles of this group by the posterior tibial nerve.

Actions.—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed it will rotate the tibia inward. It is especially called into action at the commencement of the act of bending the knee, inasmuch as it produces a slight inward rotation of the tibia, which is essential in the early stage of this movement. The Tibialis posticus is a direct extensor of the tarsus upon the leg; acting in conjunction with the Tibialis anticus, it turns the sole of the foot inward, antagonizing the Peroneus longus, which turns it outward. The Flexor longus digitorum and Flexor longus hallucis are the direct flexors of the phalanges, acting as do the similar muscles of the hand, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking or in standing on tiptoe.

In consequence of the oblique direction of the tendon of the long flexor the toes would be drawn inward were it not for the Flexor accessorius muscle, which is inserted into the outer side of its tendon and draws it to the middle line of the foot during its action. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula perpendicularly.

¹ That is, in the order of dissection of the sole of the foot.
upon the ankle-joint. They also serve to raise these bones from the oblique position they assume in the stooping posture.

Outer or Fibular Region.

**Peroneus longus.**

**Peroneus brevis.**

**Dissection.**—The muscles are readily exposed by removing the fascia covering their surface, from below upward, in the line of direction of their fibres.

The **Peroneus longus** is situated at the upper part of the outer side of the leg, and is the more superficial of the two muscles. It arises from the head and upper two-thirds of the outer surface of the shaft of the fibula, from the deep surface of the fascia, and from the intermuscular septa between it and the muscles on the front, and those on the back of the leg. It terminates in a long tendon which passes behind the outer malleolus, in a groove common to it and the Peroneus brevis, the groove being converted into a canal by a fibrous band, and the tendons invested by a common synovial membrane; it is then reflected, obliquely forward, across the outer side of the os calcis, being contained in a separate fibrous sheath lined by a prolongation of the synovial membrane from that which lines the groove behind the malleolus. Having reached the outer side of the cuboid bone, it runs in a groove on the under surface of that bone, which is converted into a canal by the long calcaneo-cuboid ligament, and is lined by a synovial membrane: the tendon then crosses obliquely the sole of the foot, and is inserted into the outer side of the base of the metatarsal bone of the great toe and the internal cuneiform bone. Occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points; first, behind the external malleolus; secondly, on the outer side of the cuboid bone; in both of these situations the tendon is thickened, and in the latter a sesamoid fibro-cartilage, or sometimes a bone, is usually developed in its substance.

**Relations.**—By its **superficial surface**, with the fascia and integument; by its **deep surface**, with the fibula, the Peroneus brevis, os calcis, and cuboid bone; by its **anterior border**, with an intermuscular septum which intervenes between it and the Extensor longus digitorum; by its **posterior border**, with an intermuscular septum which separates it from the Soleus above and the Flexor longus hallucis below.

The **Peroneus brevis** lies beneath the Peroneus longus, and is shorter and smaller than it. It arises from the lower two-thirds of the external surface of the shaft of the fibula, internal to the Peroneus longus, and from the intermuscular septa separating it from the adjacent muscles on the front and back part of the leg. The fibres pass vertically downward, and terminate in a tendon which runs in front of that of the preceding muscle through the same groove, behind the external malleolus, being contained in the same fibrous sheath and lubricated by the same synovial membrane. It then passes through a separate sheath on the outer side of the os calcis, above that for the tendon of the Peroneus longus, and is finally inserted into the tuberosity at the base of the metatarsal bone of the little toe, on its outer side.

**Relations.**—By its **superficial surface**, with the Peroneus longus and the fascia of the leg and foot; by its **deep surface**, with the fibula and outer side of the os calcis.

**Nerves.**—The Peroneus longus and brevis are supplied by the musculo-cutaneus branch of the external popliteal nerve.

**Actions.**—The Peroneus longus and brevis extend the foot upon the leg in conjunction with the Tibialis posticus, antagonizing the Tibialis anticus and Peroneus tertius, which are flexors of the foot. The Peroneus longus also everts the sole of the foot; hence the extreme eversion occasionally observed in fracture of the lower end of the fibula, where that bone offers no resistance to the action of this muscle. Taking their fixed point below, the Peronei serve to steady the leg upon the foot. This is especially the case in standing upon one leg, when the
tendency of the superincumbent weight is to throw the leg inward: the Peroneus longus overcomes this tendency by drawing on the outer side of the leg, and thus maintains the perpendicular direction of the limb.

**Surgical Anatomy.**—The student should now consider the position of the tendons of the various muscles of the leg, their relation with the ankle-joint and surrounding blood-vessels, and especially their action upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as club-foot. The most simple and, common deformity, and one that is rarely, if ever, congenital, is the talipes equinus, the heel being raised by rigidity and contraction of the Gastrocnemius muscle, and the patient walking upon the ball of the foot. In the talipes varus the foot is forcibly adducted and the inner side of the sole raised, sometimes to a right angle with the ground, by the action of the Tibialis anticus and posticus. In the talipes valgus the outer edge of the foot is raised by the Peronei muscles, and the patient walks on the inner ankle. In the talipes calcaneus the toes are raised by the extensor muscles, the heel is depressed, and the patient walks upon it. Other varieties of deformity are met with, as the talipes equino-varus, equino-valgus, and calcaneo-valgus, whose names sufficiently indicate their nature. Of these, the talipes equino-varus is the most common congenital form: the heel is raised by the tendo Achillis, the inner border of the foot drawn upward by the Tibialis anticus, the anterior two-thirds twisted inward by the Tibialis posticus, and the arch increased by the contraction of the plantar fascia, so that the patient walks on the middle of the outer border of the foot. Each of these deformities may be successfully relieved (after other remedies fail) by division of the opposing tendons and fascia: by this means the foot regains its proper position, and the tendons heal by the organization of lymph thrown out between the divided ends. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp-pointed knife inserted beneath it.

Rupture of a few of the fibres of the Gastrocnemius or rupture of the Plantaris tendon not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn tennis, and is hence known as “lawn-tennis leg.” The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The tendo Achillis is also sometimes ruptured. It is stated that John Hunter ruptured his tendo Achillis whilst dancing at the age of forty.

**THE FOOT.**

The fibrous bands which bind down the tendons in front of and behind the ankle in their passage to the foot should now be examined; they are termed the annular ligaments, and are three in number—anterior, internal, and external.

The **Anterior Annular Ligament** consists of a superior or vertical portion, which binds down the extensor tendons as they descend on the front of the tibia and fibula, and an inferior or horizontal portion, which retains them in connection with the tarsus, the two portions being connected by a thin intervening layer of fascia. The vertical portion is attached externally to the lower end of the fibula, internally to the tibia, and above is continuous with the fascia of the leg; it contains only one synovial sheath, for the tendon of the Tibialis anticus, the other tendons and the anterior tibial vessels and nerve passing beneath it, but without any distinct synovial sheath. The horizontal portion is attached externally to the upper surface of the os calcis, in front of the depression for the interosseous ligament; it passes upward and inward as a double layer, one lamina passing in front, and the other behind, the Peroneus tertius and Extensor longus digitorum. At the inner border of the latter tendon these two layers join together, forming a sort of loop or sheath in which the tendons are enclosed, surrounded by a synovial membrane. From the inner extremity of this loop two bands are given off: one passes upward and inward to be attached to the internal malleolus, passing over the Extensor proprius hallucis and vessels and nerves, but enclosing the Tibialis anticus and its synovial sheath by a splitting of its fibres. The other limb passes downward and inward to be attached to the navicular and internal cuneiform bones, and passes over both the tendon of the Extensor proprius hallucis and the Tibialis anticus, and also the vessels and nerves. These two tendons are contained in separate synovial sheaths situated beneath the ligament. It will thus be seen that the horizontal portion of the ligament is like the letter Y, the foot of the letter being attached to the os calcis, and the two diverging arms to the tibia and navicular and internal cuneiform respectively.

The **Internal Annular Ligament** is a strong fibrous band which extends from the inner malleolus above to the internal margin of the os calcis below, converting
a series of grooves in this situation into canals for the passage of the tendons of the Flexor muscles and vessels into the sole of the foot. It is continuous by its upper border with the deep fascia of the leg, and by its lower border with the plantar fascia and the fibres of origin of the Abductor hallucis muscle. The three canals which it forms transmit, from within outward, first, the tendon of the Tibialis posticus; second, the tendon of the Flexor longus digitorum; then the posterior tibial vessels and nerve, which run through a broad space beneath the ligament; lastly, in a canal formed partly by the astragalus, the tendon of the Flexor longus hallucis. Each of these canals is lined by a separate synovial membrane.

The External Annular Ligament extends from the extremity of the outer malleolus to the outer surface of the os calcis: it binds down the tendons of the Peronei muscles in their passage beneath the outer ankle. The two tendons are enclosed in one synovial sac.

Dissection of the Sole of the Foot.—The foot should be placed on a high block with the sole uppermost, and firmly secured in that position. Carry an incision round the heel and along the inner and outer borders of the foot to the great and little toes. This incision should divide the integument and thick layer of granular fat beneath until the fascia is visible; the skin and fat should then be removed from the fascia in a direction from behind forward, as seen in Fig. 328.

The Plantar Fascia, the densest of all the fibrous membranes, is of great strength, and consists of dense pearly-white glistening fibres, disposed, for the most part, longitudinally: it is divided into a central and two lateral portions.

The central portion, the thickest, is narrow behind and attached to the inner tubercle of the os calcis, behind the origin of the Flexor brevis digitorum, and, becoming broader and thinner in front, divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes divides opposite the metatarso-phalangeal articulation into two strata, superficial and deep. The superficial stratum is inserted into the skin of the transverse sulcus which divides the toes from the sole. The deeper stratum divides into two slips which embrace the sides of the flexor tendons of the toes, and blend with the sheaths of the tendons, and laterally with the transverse metatarsal ligament, thus forming a series of arches through which the tendons of the short and long flexors pass to the toes. The intervals left between the five processes allow the digital vessels and nerves and the tendons of the Lumbricales muscles to become superficial. At the point of division of the fascia into processes and slips numerous transverse fibres are superadded, which serve to increase the strength of the fascia at this part by binding the processes together and connecting them with the integument. The central portion of the plantar fascia is continuous with the lateral portions at each side, and sends upward into the foot, at their point of junction, two strong vertical intermuscular septa, broader in front than behind, which separate the middle from the external and internal plantar group of muscles; from these, again, thinner transverse septa are derived, which separate the various layers of muscles in this region. The upper surface of this fascia gives attachment behind to the Flexor brevis digitorum muscle.

The lateral portions of the plantar fascia are thinner than the central piece, and cover the sides of the foot.

The outer portion covers the under surface of the Abductor minimi digiti; it is thick behind, thin in front, and extends from the os calcis, forward, to the base of the fifth metatarsal bone, into the outer side of which it is attached; it is continuous internally with the middle portion of the plantar fascia, and externally with the dorsal fascia.

The inner portion is very thin, and covers the Abductor hallucis muscle; it is attached behind to the internal annular ligament, and is continuous around the side of the foot with the dorsal fascia, and externally with the middle portion of the plantar fascia.

The Muscles of the Foot are found in two regions: 1. On the dorsum; 2. On the plantar surface.
1. Dorsal Region.

The Fascia on the dorsum of the foot is a thin membranous layer continuous above with the anterior margin of the annular ligament; it becomes gradually lost opposite the heads of the metatarsal bones, and on each side blends with the lateral portions of the plantar fascia; it forms a sheath for the tendons placed on the dorsum of the foot. On the removal of this fascia the muscles and tendons of the dorsal region of the foot are exposed.

The Extensor brevis digitorum (Fig. 330) is a broad thin muscle which arises from the fore part of the upper and outer surfaces of the os calcis, in front of the groove for the Peroneus brevis, from the external calcaneo-astragaloid ligament, and from the horizontal portion of the anterior annular ligament. It passes obliquely across the dorsum of the foot, and terminates in four tendons. The innermost, which is the largest, is inserted into the dorsal surface of the base of the first phalanx of the great toe, crossing the Dorsalis pedis artery; the other three, into the outer sides of the long extensor tendons of the second, third, and fourth toes.

Relations.—By its superficial surface, with the fascia of the foot, the tendons of the Extensor longus digitorum and Extensor proprius hallucis; by its deep surface, with the tarsal and metatarsal bones and the Dorsal interossei muscles.

Nerves.—It is supplied by the anterior tibial nerve.

Actions.—The Extensor brevis digitorum is an accessory to the long Extensor, extending the first phalanges of all four inner toes. The obliquity of its direction counteracts the oblique movement given to the toes by the long Extensor, so that, both muscles acting together, the toes are evenly extended.

2. Plantar Region.

The muscles in the plantar region of the foot may be divided into three groups, in a similar manner to those in the hand. Those of the internal plantar region are connected with the great toe, and correspond with those of the thumb; those of the external plantar region are connected with the little toe, and correspond with those of the little finger; and those of the middle plantar region are connected with the tendons intervening between the two former groups. But in order to facilitate the dissection of these muscles it will be found more convenient to divide them into four layers, as they present themselves, in the order in which they are successively exposed.

First Layer.

Abductor hallucis. Flexor brevis digitorum.
Abductor minimi digiti.

Dissection.—Remove the fascia on the inner and outer sides of the foot, commencing in front over the tendons and proceeding backward. The central portion should be divided transversely in the middle of the foot, and the two flaps dissected forward and backward.

The Abductor hallucis lies along the inner border of the foot. It arises from the inner tuberele on the under surface of the os calcis; from the internal annular ligament; from the plantar fascia; and from the intermuscular septum between it and the Flexor brevis digitorum. The fibres terminate in a tendon which is inserted, together with the innermost tendon of the Flexor brevis hallucis, into the inner side of the base of the first phalanx of the great toe.

Relations.—By its superficial surface, with the plantar fascia; by its deep surface, with the Flexor brevis hallucis, the Flexor accessorius, and the tendons of the Flexor longus digitorum and Flexor longus hallucis, the Tibialis anticus and posticus, the plantar vessels and nerves, and the articulations of the tarsus.

The Flexor brevis digitorum (perforatus) lies in the middle of the sole of the foot, immediately beneath¹ the plantar fascia, with which it is firmly united. It

¹ That is, in order of dissection of the sole of the foot.
arises by a narrow tendinous process, from the inner tubercle of the os calcis, from the central part of the plantar fascia, and from the intermuscular septa between it and the adjacent muscles. It passes forward, and divides into four tendons. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor longus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying long flexor tendon. Finally, they divide a second time, to be inserted into the sides of the second phalanges about their middle. The mode of division of the tendons of the Flexor brevis digitorum and their insertion into the phalanges is analogous to the Flexor sublimis in the hand.

**Relations.**—By its superficial surface, with the plantar fascia; by its deep surface, with the Flexor accessorius, the Lumbricales, the tendons of the Flexor longus digitorum, and the external plantar vessels and nerve, from which it is separated by a thin layer of fascia. The outer and inner borders are separated from the adjacent muscles by means of vertical prolongations of the plantar fascia.

**Fibrous Sheaths of the Flexor Tendons.**—These are not so well marked as in the fingers. The flexor tendons of the toes as they run along the phalanges are retained against the bones by a fibrous sheath, forming osseo-aponeurotic canals. These sheaths are formed by strong fibrous bands which arch across the tendons and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely, but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane which is reflected on the contained tendon.

The **Abductor minimi digit** lies along the outer border of the foot. It arises, by a very broad origin, from the outer tubercle of the os calcis, from the under surface of the os calcis in front of both tubercles, from the fore part of the inner tubercle, from the plantar fascia and the intermuscular septum between it and the Flexor brevis digitorum. Its tendon, after gliding over a smooth facet on the under surface of the base of the fifth metatarsal bone, is inserted with the short Flexor of the little toe into the outer side of the base of the first phalanx of the little toe.

**Relations.**—By its superficial surface, with the plantar fascia; by its deep surface, with the Flexor accessorius, the Flexor brevis minimi digit, the long plantar ligament, and the tendon of the Peroneus longus. On its inner side are the external plantar vessels and nerve, and it is separated from the Flexor brevis digitorum by a vertical septum of fascia.

**Dissection.**—The muscles of the superficial layer should be divided at their origin by inserting the knife beneath each, and cutting obliquely backward, so as to detach them from the bone; they should then be drawn forward, in order to expose the second layer, but not cut.
in their insertion. The two layers are separated by a thin membrane, the deep plantar fascia, on the removal of which is seen the tendon of the Flexor longus digitorum, the Flexor accessorius, the tendon of the Flexor longus hallucis, and the Lumbricales. The long flexor tendons cross each other at an acute angle, the Flexor longus hallucis running along the inner side of the foot, on a plane superior to that of the Flexor longus digitorum, the direction of which is obliquely outward.

**Second Layer.**

Flexor accessorius. Lumbricales.

The Flexor accessorius arises by two heads; the inner or larger, which is muscular, being attached to the inner concave surface of the os calcis, and to the inferior calcaneo-navicular ligament; the outer head, flat and tendinous, to the under surface of the os calcis, in front of its outer tubercle, and to the long plantar ligament; the two portions join at an acute angle, and are inserted into the outer margin and upper and under surfaces of the tendon of the Flexor longus digitorum, forming a kind of groove in which the tendon is lodged.¹

**Relations.**—By its superficial surface, with the muscles of the superficial layer, from which it is separated by the external plantar vessels and nerves; by its deep surface, with the os calcis and long calcaneocuboid ligament.

The Lumbricales are four small muscles accessory to the tendons of the Flexor longus digitorum: they arise from the tendons of the long Flexor, as far back as their angle of division, each arising from two tendons, except the internal one. Each muscle terminates in a tendon, which passes forward on the inner side of each of the lesser toes, and is inserted into the expansion of the long Extensor and base of the first phalanx of the corresponding toe.

**Dissection.**—The flexor tendons should be divided at the back part of the foot, and the Flexor accessorius at its origin, and drawn forward, in order to expose the third layer.

**Third Layer.**

Flexor brevis hallucis.
Adductor obliquus hallucis.
Flexor brevis minimi digitii.
Adductor transversus hallucis.

The Flexor brevis hallucis arises, by a pointed tendinous process, from the inner border of the cuboid bone, from the contiguous portion of the external cuneiform, and from the prolongation of the tendon of the Tibialis posticus, which

¹ According to Turner, the fibres of the Flexor accessorius end in aponeurotic bands, which contribute slips to the second, third, and fourth digits.
is attached to that bone. The muscle divides, in front, into two portions, which are inserted into the inner and outer sides of the base of the first phalanx of the great toe, a sesamoid bone being developed in each tendon at its insertion. The inner portion of this muscle is blended with the Adductor hallucis previous to its insertion, the outer with the Adductor obliquus hallucis, and the tendon of the Flexor longus hallucis lies in a groove between them.

**Relations.**—By its superficial surface, with the Adductor hallucis, the tendon of the Flexor longus hallucis, and plantar fascia; by its deep surface, with the tendon of the Peroneus longus and metatarsal bone of the great toe; by its inner border, with the Adductor hallucis; by its outer border, with the Adductor obliquus hallucis.

The Adductor obliquus hallucis is a large, thick, fleshy mass passing obliquely across the foot and occupying the hollow space between the four inner metatarsal bones. It arises from the tarsal extremities of the second, third and fourth metatarsal bones, and from the sheath of the tendon of the Peroneus longus, and is inserted, together with the outer portion of the Flexor brevis hallucis, into the outer side of the base of the first phalanx of the great toe.

The small muscles of the great toe, the Adductor, Flexor brevis, Adductor obliquus, and Adductor transversus, like the similar muscles of the thumb, give off fibrous expansions, at their insertions, to blend with the long Extensor tendon.

The Flexor brevis minimi digiti lies on the metatarsal bone of the little toe, and much resembles one of the Interossei. It arises from the base of the metatarsal bone of the little toe, and from the sheath of the Peroneus longus; its tendon is inserted into the base of the first phalanx of the little toe on its outer side.

**Relations.**—By its superficial surface, with the plantar fascia and tendon of the Abductor minimi digiti; by its deep surface, with the fifth metatarsal bone.

The Adductor transversus hallucis (*Transversus pedis*) is a narrow, flat, muscular fasciculus, stretched transversely across the heads of the metatarsal bones, between them and the flexor tendons. It arises from the inferior metatarso-phalangeal ligaments of the three outer toes, sometimes only from the third and fourth and from the transverse ligament of the metatarsus; and is inserted into the outer side of the first phalanx of the great toe, its fibres being blended with the tendon of insertion of the Adductor obliquus hallucis.

**Relations.**—By its superficial surface, with the tendons of the long and short Flexors and Lumbricales; by its deep surface, with the Interossei.
Fourth Layer.

The Interossei.

The Interossei muscles in the foot are similar to those in the hand, with this exception, that they are grouped around the middle line of the second toe, instead of the middle line of the third finger, as in the hand. They are seven in number, and consist of two groups, dorsal and plantar.

The Dorsal interossei, four in number, are situated between the metatarsal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metatarsal bones, between which they are placed; their tendons are inserted into the bases of the first phalanges, and into the aponeurosis of the common extensor tendon. In the angular interval left between the heads of each muscle at its posterior extremity the perforating arteries pass to the dorsum of the foot, except in the First interosseous muscle, where the interval allows the passage of the communicating branch of the dorsalis pedis artery. The First dorsal interosseous muscle is inserted into the inner side of the second toe; the other three are inserted into the outer sides of the second, third, and fourth toes.

The Plantar interossei, three in number, lie beneath, rather than between, the metatarsal bones. They are single muscles, and are each connected with but one metatarsal bone. They arise from the base and inner sides of the shaft of the third, fourth, and fifth metatarsal bones, and are inserted into the inner sides of the bases of the first phalanges of the same toes, and into the aponeurosis of the common extensor tendon.

Nerves.—The Flexor brevis digitorum, the Flexor brevis and Abductor hallucis, and the two inner Lumbricales are supplied by the internal plantar nerve; all the other muscles in the sole of the foot by the external plantar. The First and Second dorsal interossei muscles receive extra filaments from the ganglionic enlargement of the anterior tibial nerve on the dorsum of the foot.

Actions.—All the muscles of the foot act upon the toes, and for purposes of description as regards their action may be grouped as Abductors, Adductors,
Flexors, or Extensors. The \textit{Abductors} are the Dorsal interossei, the Abductor hallucis, and the Abductor minimi digiti. The Dorsal interossei are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe inward, toward the great toe; the second muscle draws the same toe, outward; the third draws the third toe, and the fourth draws the fourth toe, in the same direction. Like the interossei in the hand, they also flex the proximal phalanges and extend the two terminal phalanges. The Abductor hallucis abducts the great toe from the others, and also flexes the proximal phalanx of this toe. And in the same way the action of the Abductor minimi digiti is twofold—as an abductor of this toe from the others, and also as a flexor of the proximal phalanx. The \textit{Adductors} are the Plantar interossei, the Adductor obliquus hallucis, and the Adductor transversus hallucis. The plantar interosseous muscles adduct the third, fourth, and fifth toes toward the imaginary line passing through the second toe, and by means of their insertion into the aponeurosis of the extensor tendon they flex the proximal phalanges and extend the two terminal phalanges. The Adductor obliquus hallucis is chiefly concerned in adducting the great toe toward the second one, but also assists in flexing this toe. The Adductor transversus hallucis approximates all the toes, and thus increases the curve of the transverse arch of the metatarsus. The \textit{Flexors} are the Flexor brevis digitorum, the Flexor accessorius, the Flexor brevis hallucis, the Flexor brevis, minimi digiti, and the Lumbricales. The Flexor brevis digitorum flexes the second phalanges upon the first, and, continuing its action, may flex the first phalanges also and bring the toes together. The Flexor accessorius assists the Long flexor of the toes, and converts the oblique pull of the tendons of that muscle into a direct backward pull upon the toes. The Flexor brevis minimi digiti flexes the little toe and draws its metatarsal bone downward and inward. The Lumbricales, like the corresponding muscles in the hand, assist in flexing the proximal phalanges, and by their insertion into the long Extensor tendon aid in straightening the two terminal phalanges. The only muscle in the Extensor group is the Extensor brevis digitorum. It extends the first phalanx of the great toe, and assists the long Extensor in extending the next three toes, and at the same time gives to the toes an outward direction when they are extended.

\textbf{Surface Form.}—Of the muscles of the thigh, those of the iliac region have no influence on surface form, while those of the anterior femoral region, being to a great extent superficial, largely contribute to the surface form of this part of the body. The \textit{Tensor vaginae femoris} produces a broad elevation immediately below the anterior portion of the crest of the ilium and behind the anterior superior spinous process. From its lower border a longitudinal groove, corresponding to the ilio-tibial band, may be seen running down the outer side of the thigh to the outer side of the knee-joint. The \textit{Sartorius} muscle, when it is brought into action by flexing the leg on the thigh and the thigh on the pelvis, and rotating the thigh outward, presents a well-marked surface form. At its upper part, where it constitutes the outer boundary of Scarpa's triangle, it forms a prominent oblique ridge, which becomes changed into a flattened plane below, and this gradually merges in a general fulness on the inner side of the knee-joint. When the Sartorius is not in action, a depression exists between the Extensor quadriiceps and the Adductor muscles, running obliquely downward and inward from the apex of Scarpa's triangle to the inner side of the knee, which corresponds to this muscle. In the depressed angle formed by the divergence of the Sartorius and Tensor vaginae femoris muscles, just below the anterior superior spinous process of the ilium, the \textit{Rectus femoris} muscle appears; and, below this, determines to a great extent the convex form of the front of the thigh. In a well-developed subject the borders of the muscle, when in action, are clearly to be defined. The \textit{Vastus externus} forms a long flattened plane on the outer side of the thigh, traversed by the longitudinal groove formed by the ilio-tibial band. The \textit{Vastus internus}, on the inner side of the lower half of the thigh, gives rise to a considerable prominence, which increases toward the knee and terminates somewhat abruptly in this situation with a full, curved outline. The \textit{Crureus} and \textit{Subcrureus} are completely hidden, and do not directly influence surface form. The \textit{Adductor musculi}, constituting the internal femoral group, are not to be individually distinguished from each other, with the exception of the upper tendon of the Adductor longus and the lower tendon of the Adductor magnus. The upper tendon of the \textit{Adductor longus}, when the muscle is in action, stands out as a prominent ridge, which runs obliquely downward and outward from the neighborhood of the pubic spine, and forms the inner boundary of a flattened triangular space on the upper part of the front of the thigh, known as Scarpa's triangle. The
lower tendon of the *Adductor magnus* can be distinctly felt as a short ridge extending down to the Adductor tubercle on the internal condyle, between the Sartorius and Vastus internus. The Adductor group of muscles fills in the triangular space at the upper part of the thigh, formed between the oblique femur and the pelvic wall, and to them is due the contour of the inner border of the thigh, the *Gracilis* largely contributing to the smoothness of the outline. These muscles are not marked off on the surface from those of the posterior femoral region by any intermuscular marking; but on the outer side of the thigh these latter muscles are defined from the Vastus externus by a distinct marking, corresponding to the external intermuscular septum. The *Gluteus maximus* and a part of the *Gluteus medius* are the only muscles of the buttck which influence surface form. The other part of the Gluteus medius, the Gluteus minimus, and the External rotators are completely hidden. The *Gluteus maximus* forms the full rounded outline of the buttck; it is more prominent behind, compressed in front, and terminates at its tendinous insertion in a depression immediately behind the great trochanter. Its lower border does not correspond to the gluteal fold, but is much more oblique, being marked by a line drawn from the side of the coccyx to the lower part of the great trochanter. From beneath the fold of the buttck the *hamstring muscles* appear, at first narrow and not well marked, but as they descend becoming more prominent and widened out, and eventually dividing into two well-marked ridges, which form the upper boundaries of the popliteal space, being formed by the tendons of the inner and outer hamstring muscles respectively. In the upper part of the thigh these muscles are not to be individually distinguished from each other, but lower down, the separation between the Semitendinosus and Semimembranosus is denoted by a slight intermuscular marking. The external hamstring tendon formed by the *Biceps* is seen as a thick cord running down to the head of the fibula. The inner hamstring tendons comprise the Semitendinosus, the Semimembranosus, and the *Gracilis*. The *Semitendinosus* is the most internal of these, and can be felt, in certain positions of the limb, as a sharp cord; the *Semimembranosus* is thick, and the *Gracilis* is situated a little farther forward than the other two. All the muscles on the front of the leg appear to a certain extent somewhere on the surface, but the form of this region is mainly dependent upon the Tibialis anticus and the Extensor longus digitisorum. The *Tibialis anticus* is well marked, and presents a fusiform enlargement at the outer side of the tibia, and projects beyond the crest of the shin-bone. From the muscular mass its tendon may be traced downward, standing out boldly, when the muscle is in action, on the front of the tibia and ankle-joint, and coursing down to its insertion along the inner border of the foot. A well-marked groove separates this muscle externally from the *Extensor longus digitisorum*, which fills up the rest of the space between the upper part of the shaft of the tibia and fibula. It does not present so bold an outline as the Tibialis anticus, and its tendon below, diverging from the tendon of the Tibialis anticus, forms a sort of plane, in which may be seen the tendon of the Extensor proprius hallucis. A groove on the outer side of the Extensor longus digitorum, seen most plainly when the muscle is in action, separates from it a slight eminence corresponding to the *Peroneus tertius*. The fleshy fibres of the *Peroneus longus* are strongly marked at the upper part of the outer side of the leg, especially when the muscle is in action. It forms a broad swelling separated by furrows from the Extensor longus digitorum in front and the *Soleus* behind. Below, the fleshy fibres terminate abruptly in a tendon which overlaps the more flattened form of the *Peroneus brevis*. At the external malleolus the tendon of the Peroneus brevis is more marked than that of the Peroneus longus. On the dorsum of the foot the tendons of the Extensor muscles, emerging from beneath the anterior annular ligament, spread out and can be distinguished in the following order: The most internal and largest is the Tibialis anticus, then the Extensor propius hallucis: next comes the Extensor longus digitorum, dividing into four tendons to the four outer toes; and lastly, most externally, is the Peroneus tertius. The flattened form of the dorsum of the foot is relieved by the rounded outline of the fleshy belly of the *Extensor brevis digitiorum*, which forms a soft fulness on the outer side of the tarsus in front of the external malleolus, and by the Dorsal interosseus, which bulge between the metatarsal bones. At the back of the knee is the popliteal space, bounded above by the tendons of the hamstring muscle; below, by the two heads of the Gastrocnemius. Below this space is the prominent fleshy mass of the calf of the leg, produced by the *Gastrocnemius* and *Soleus*. When these muscles are in action, as in standing on tiptoe, the borders of the Gastrocnemius are well defined, presenting two curved lines, which converge to the tendon of insertion. Of these borders, the inner is more prominent than the outer. The fleshy mass of the calf terminates somewhat abruptly below in the tendo Achilles, which stands out prominently on the lower part of the back of the leg. It presents a somewhat tapering form in the upper three-fourths of its extent, but widens out slightly below. When the muscles of the calf are in action, the lateral portions of the *Soleus* may be seen, forming a dimpled line with the long extensor muscle above it. The tibial crest, behind the inner border of the lower part of the shaft of the tibia a well-marked ridge, produced by the tendon of the Tibialis posterior, is visible when this muscle is in a state of contraction.

On the sole of the foot the superficial layer of muscles influences surface form; the *Abductor minimi digiti* most markedly. This muscle forms a narrow rounded elevation along the outer border of the foot, while the *Abductor hallucis* does the same, though to a less extent, on the inner side. The *Flexor brevis digitorum*, bound down by the plantar fascia, is not very apparent; it produces a flattened form, covered by the thickened skin of the sole, which is here thrown into numerous wrinkles.
SURGICAL ANATOMY OF THE LOWER EXTREMITY.

The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fractures are selected for illustration and description.

In fracture of the neck of the femur internal to the capsular ligament (Fig. 338) the characteristic marks are slight shortening of the limb and eversion of the foot, neither of which symptoms occurs, however, in some cases until some time after the injury. The eversion is caused by the weight of the limb rotating it outward. The shortening is produced by the action of the Glutei, and by the Rectus femoris in front and the Biceps, Semitendinosus, and Semimembranosus behind.

In fracture of the femur just below the trochanters (Fig. 339) the upper fragment, the portion chiefly displaced, is tilted forward almost at right angles with the pelvis by the combined action of the Psoas and Iliacus, and, at the same time, everted and drawn outward by the External rotator and Glutei muscles, causing a marked prominence at the upper and outer side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, in consequence of the lower fragment being drawn upward by the rectus in front, and the Biceps, Semimembranosus, and Semitendinosus behind, and, at the same time, everted, and the upper end thrown outward and the lower inward by the Pectineus and Adductor muscles. This fracture may be reduced in two different methods: either by direct relaxation of all the opposing muscles, to effect which the limb should be placed on a double inclined plane; or by overcoming the contraction of the muscles by continued extension, which may be effected by means of the long splint.

Oblique fracture of the femur immediately above the condyles (Fig. 340) is a formidable injury, and attended with considerable displacement. On examination of the limb the lower fragment may be felt deep in the popliteal space, being drawn backward by the Gastrocnemius and Plantaris muscles, and upward by the posterior Femoral and Rectus muscles. The pointed end of the upper fragment is drawn inward by the Pectineus and Adductor muscles, and tilted forward by the Psoas and Iliacus, piercing the Rectus muscle and occasionally the integument. Relaxation of these muscles and direct approximation of the broken fragments are effected by placing the limb on a double inclined plane. The greatest care is requisite in keeping the pointed extremity of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed, from the Rectus muscle being held down by the fractured end of the bone, and from the patella, when elevated, being drawn upward against the projecting fragment.

In fracture of the patella (Fig. 341) the fragments are separated by the effusion which takes place into the joint, and possibly by the action of the Quadriceps extensor; the extent of separation of the two
fragments depending upon the degree of laceration of the ligamentous structures around the bone.

In oblique fracture of the shaft of the tibia (Fig. 342), if the fracture has taken place obliquely from above, downward and forward, the fragments ride over one another, the lower fragments being drawn backward and upward by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forward immediately beneath the integument, often protruding through it and rendering the fracture a compound one. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forward, riding upon the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counter-extension at the knee, the fragments may be brought into apposition. It is often necessary, however, in compound fracture, to remove a portion of the projecting bone with the saw before complete adaptation can be effected.

Fracture of the fibula with dislocation of the foot outward (Fig. 343), commonly known as "Pott's Fracture," is one of the most frequent injuries of the ankle-joint. The end of the tibia is displaced from the corresponding surface of the astragalus; the internal lateral ligament is ruptured; and the inner malleolus projects inward beneath the integument, which is tightly stretched over it and in danger of bursting. The fibula is broken, usually from two to three inches above the ankle, and occasionally that portion of the tibia with which it is more directly connected below; the foot is everted by the action of the Peroneus longus, its inner border resting upon the ground, and at the same time the heel is drawn up by the muscles of the calf. This injury may be at once reduced by flexing the leg at right angles with the thigh, which relaxes all the opposing muscles, and by making extension from the ankle and counter-extension at the knee.
THE ARTERIES.

THE Arteries are cylindrical tubular vessels which serve to convey blood from both ventricles of the heart to every part of the body. These vessels were named arteries (ἀέρ, air; τροφίν, to contain) from the belief entertained by the ancients that they contained air. To Galen is due the honor of refuting this opinion; he showed that these vessels, though for the most part empty after death, contain blood in the living body.

The pulmonary artery, which arises from the right ventricle of the heart, carries venous blood directly into the lungs, whence it is returned by the pulmonary veins into the left auricle. This constitutes the lesser or pulmonic circulation. The great artery which arises from the left ventricle, the aorta, conveys arterial blood to the body generally, whence it is brought back to the right side of the heart by means of the veins. This constitutes the greater or systemic circulation.

The distribution of the systemic arteries is like a highly ramified tree, the common trunk of which, formed by the aorta, commences at the left ventricle of the heart, the smallest ramifications corresponding to the circumference of the body and the contained organs. The arteries are found in nearly every part of the body, with the exception of the hairs, nails, epidermis, cartilages, and cornea; and the larger trunks usually occupy the most protected situations, running, in the limbs, along the flexor side, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as we observe in the celiac and thyroid axes; or the vessel may give off several branches in succession, and still continue as the main trunk, as is seen in the arteries of the limbs; but the usual division is dichotomous; as, for instance, the aorta dividing into the two common iliacs, and the common carotid into the external and internal.

The branches of arteries arise at very variable angles: some, as the superior intercostal arteries from the aorta, arise at an obtuse angle; others, as the lumbar arteries, at a right angle; or, as the spermatic, at an acute angle. An artery from which a branch is given off is smaller in size, but retains a uniform diameter until a second branch is derived from it. A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined area of all the arterial branches greatly exceeds the area of the aorta; so that the arteries collectively may be regarded as a cone, the apex of which corresponds to the aorta, the base to the capillary system.

The arteries, in their distribution, communicate freely with one another, forming what is called an anastomosis (ἀνάστομος, to unite; στόμα, mouth), or inosculated; and this communication is very free between the large as well as between the smaller branches. The anastomosis between trunks of equal size is found where great freedom and activity of the circulation are requisite, as in the brain; here the two vertebral arteries unite to form the basilar, and the two internal carotid arteries are connected by a short communicating trunk; it is also found in the abdomen, the intestinal arteries having very free anastomoses between their larger
branches. In the limbs the anastomoses are most frequent and of largest size around the joints, the branches of an artery above freely inosculating with branches from the vessels below; these anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a collateral circulation is established after the application of a ligature to an artery for the cure of aneurism. The smaller branches of arteries anastomose more frequently than the larger, and between the smallest twigs these inosculations become so numerous as to constitute a close network that pervades nearly every tissue of the body.

Throughout the body generally the larger arterial branches pursue a perfectly straight course, but in certain situations they are tortuous; thus, the facial artery in its course over the face, and the arteries of the lips, are extremely tortuous in their course, to accommodate themselves to the movements of the parts. The uterine arteries are also tortuous, to accommodate themselves to the increase of size which the organ undergoes during pregnancy. Again, the internal carotid and vertebral arteries, previous to their entering the cavity of the skull, describe a series of curves, which are evidently intended to diminish the velocity of the current of blood by increasing the extent of surface over which it moves and adding to the amount of impediment which is produced by friction.

The arteries are dense in structure, of considerable strength, highly elastic, and, when divided, they preserve, although empty, their cylindrical form.

The minute structure of these vessels has been described in the chapter on General Anatomy.

In the description of the arteries we shall first consider the efferent trunk of the pulmonic circulation, the pulmonary artery, and then the efferent trunk of the systemic circulation, the aorta and its branches.

**THE PULMONARY ARTERY** (Fig. 344).

The **pulmonary artery** conveys the venous blood from the right side of the heart to the lungs. It is a short, wide vessel, about two inches in length, arising from the left side of the base of the right ventricle, in front of the aorta. It passes obliquely upward and backward, passing at first in front of, and then to the left of, the ascending aorta as far as the under surface of the transverse aorta, where it divides into two branches of nearly equal size—the right and left pulmonary arteries.

**Relations.**—The whole of this vessel is contained, together with the ascending aorta, in the pericardium, being enclosed with it in a tube of serous membrane, continued upward from the base of the heart, and has attached to it, above, the fibrous layer of the membrane. Behind, it rests at first upon the ascending aorta, and higher up lies in front of the left auricle. On each side of its origin is the appendix of the corresponding auricle and a coronary artery; and higher up it passes to the left side of the ascending aorta.

The **right pulmonary artery**, longer and larger than the left, pierces the pericardium and runs horizontally outward, behind the ascending aorta and superior vena cava, to the root of the right lung, where it divides into two branches, of which the lower, which is the smaller, supplies the lower lobe; the upper supplies the upper lobe, giving a branch to the middle lobe.

The **left pulmonary artery**, shorter and somewhat smaller than the right, pierces the pericardium and passes horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches for the two lobes.

The root of the left pulmonary artery is connected to the under surface of the arch of the aorta (transverse aorta) by a short fibrous cord, the remains of a vessel peculiar to foetal life, the ductus arteriosus.

The terminal branches of the pulmonary artery will be described with the anatomy of the lung.
The aorta (ἀόρτη, arteria magna) is the main trunk of a series of vessels which convey the oxygenated blood to every part of the body for its nutrition. This vessel commences at the upper part of the left ventricle, and, after ascending for a short distance, arches backward to the left side, over the root of the left lung, then descends within the thorax on the left side of the vertebral column, passes through the aortic opening in the Diaphragm, and, entering the abdominal cavity, terminates, considerably diminished in size, opposite the fourth lumbar vertebra,

where it divides into the right and left common iliac arteries. Hence its division into the ascending aorta, the arch of the aorta or transverse aorta, and the descending aorta, which last is again divided into thoracic aorta and abdominal aorta, from the position of these parts.

**THE ASCENDING AORTA.**

The ascending aorta is about two inches in length. It commences at the upper part of the left ventricle, on a level with the lower border of the third costal cartilage behind the left half of the sternum; it passes obliquely upward, forward,
and to the right in the direction of the heart's axis, as high as the upper border of the second right costal cartilage, describing a slight curve in its course, and being situated, when distended, about a quarter of an inch behind the posterior surface of the sternum. A little above its commencement it is somewhat enlarged, and presents three small dilatations, called the sinuses of the aorta (sinuses of Valsalva), opposite to which are attached the three semilunar valves, which serve the purpose of preventing any regurgitation of blood into the cavity of the ventricle. A section of the aorta opposite this part has a somewhat triangular figure, but below the attachment of the valves it is circular. This portion of the aorta is contained in the cavity of the pericardium, and, together with the pulmonary artery, is invested in a tube of serous membrane, continued on to them from the surface of the heart.

**Relations.**—The ascending aorta is covered at its commencement by the trunk of the pulmonary artery and the right auricular appendix, and, higher up, is separated from the sternum by the pericardium over which lie:—the right pleura, and anterior margin of right lung, some loose areolar tissue, and the remains of the thymus gland; *behind*, it rests upon the right pulmonary artery and left auricle. On the *right side* it is in relation with the superior vena cava and right auricle; on the *left side*, with the main pulmonary artery.

**Branches of the Ascending Aorta.**

The only branches of the ascending aorta are the two coronary arteries. They supply the heart, and are two in number, right and left, arising near the commencement of the aorta immediately above the free margin of the semilunar valves.

**The Coronary Arteries.**

The **Right Coronary Artery**, about the size of a crow's quill, arises from the aorta immediately above the free margin of the anterior semilunar valve. It passes forward between the pulmonary artery and the right auricular appendix, then runs obliquely to the right side in the groove between the right auricle and ventricle, and, curving around the right border of the heart, runs along its posterior surface as far as the posterior interventricular groove, where it divides into two branches, one of which (*transverse*) continues onward in the groove between the left auricle and ventricle, and anastomoses with the left coronary; the other (*descending*) descends along the posterior interventricular furrow, supplying branches to both ventricles and to the septum, and anastomosing at the apex of the heart with the descending branches of the left coronary.

This vessel sends a large branch (*marginal*) along the thin margin of the right ventricle to the apex, and numerous small branches to the right auricle and ventricle, and the commencement of the pulmonary artery (*infundibular*).

The **Left Coronary**, larger than the former, arises immediately above the free
edge of the left posterior semilunar valve, a little higher than the right; it passes forward between the pulmonary artery and the left auricular appendix, and divides into two branches. Of these, one (transverse) passes transversely outward in the left auriculo-ventricular groove, and winds around the left border of the heart into its posterior surface, where it anastomoses with the transverse branch of the right coronary; the other (descending) descends along the anterior interventricular groove to the apex of the heart, where it anastomoses with the descending branches of the right coronary. The left coronary supplies the left auricle and its appendix, both ventricles, and numerous small branches to the pulmonary artery, and commencement of the aorta.¹

Peculiarities.—These vessels occasionally arise by a common trunk, or their number may be increased to three, the additional branch being of small size. More rarely, there are two additional branches.

**THE ARCH OF THE AORTA.**

The arch, or transverse aorta, commences at the upper border of the second chondro-sternal articulation of the right side, and passes from right to left, and from before backward, to the left side of the lower border of the fourth dorsal vertebra behind. Its upper border is usually about an inch below the upper margin of the sternum.

Relations.—Its anterior surface is covered by the pleura and lungs and the remains of the thymus gland, and crossed toward the left side by the left pneumogastric and phrenic nerves and superior cardiac branches of the left sympathetic, and by the left superior intercostal vein. Its posterior surface lies on the trachea, just above its bifurcation, on the great, or deep, cardiac plexus, the esophagus, thoracic duct, and left recurrent laryngeal nerve. Its upper border is in relation with the left innominate vein, and from its upper part are given off the innominate, left common carotid, and left subclavian arteries. Its lower border is in relation with the bifurcation of the pulmonary artery, the remains of the ductus arteriosus, which is connected with the left division of that vessel, and the superficial cardiac plexus; the left recurrent laryngeal nerve winds round it from before backward, whilst the left bronchus passes below it.

**Peculiarities.**—The height to which the aorta rises in the chest is usually about an inch below the upper border of the sternum; but it may ascend nearly to the top of that bone. Occasionally it is found an inch and a half, more rarely two or even three inches, below this point.

¹ According to Dr. Samuel West, there is a very free and complete anastomosis between the two coronary arteries (Lancet, June 2, 1853, p. 945). This, however, is not the view generally held by anatomists, for, with the exception of the anastomosis mentioned above in the auriculo-ventricular and interventricular grooves, it is believed that the two arteries only communicate by very small vessels in the substance of the heart.
In Direction.—Sometimes the aorta arches over the root of the right instead of the left lung, as in birds, and passes down on the right side of the spine. In such cases all of the viscera of the thoracic and abdominal cavities are transposed. Less frequently, the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the spine, this peculiarity not being accompanied by any transposition of the viscera.

In Conformation.—The aorta occasionally divides, as in some quadrupeds, into an ascending and descending trunk, the former of which is directed vertically upward, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides soon after its origin into two branches, which soon reunite. In one of these cases the oesophagus and trachea were found to pass through the interval left by their division; this is the normal condition of the vessel in the reptilia.

Surgical Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from aneurism of this part.

It will be remembered that the ascending aorta is contained in the pericardium, just behind the sternum, being crossed at its commencement by the pulmonary artery and right auricular appendix, and having the root of the right lung behind, the vena cava on the right side, and the pulmonary artery and left auricle on the left side.

Aneurism of the ascending aorta, in the situation of the aortic sinuses, in the great majority of cases, affects the right anterior sinus; this is mainly owing to the fact that the regurgitation of blood upon the sinuses takes place chiefly on the right anterior aspect of the vessel. As the aneurismatic sac enlarges it may compress any or all of the structures in immediate proximity with it, but chiefly projects toward the right anterior side, and, consequently, interferes mainly with those structures that have a corresponding relation with the vessel. In the majority of cases it bursts into the cavity of the pericardium, the patient suddenly drops down dead, and, upon a post-mortem examination, the pericardial sac is found full of blood; or it may compress the right auricle, or the pulmonary artery, and adjoining part of the right ventricle, and open into one or the other of these parts, or may press upon the superior vena cava.

Aneurism of the ascending aorta, originating above the sinuses, most frequently implicates the right anterior wall of the vessel; this is probably mainly owing to the blood being impelled against this part. The direction of the aneurism is also chiefly toward the right of the median line. If it attains a large size and projects forward, it may absorb the sternum and the cartilages of the ribs, usually on the right side, and appear as a pulsating tumor on the front of the chest, just below the manubrium; or it may burst into the pericardium, or may compress or open into the right lung, the trachea, bronchi, or oesophagus.

Regarding the transverse aorta, the student is reminded that the vessel lies on the trachea, the oesophagus, and thoracic duct; that the recurrent laryngeal nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper extremities. Now, an aneurismatic tumor, taking origin from the posterior part or right aspect of the vessel, its most usual site, may press upon the trachea, impede the breathing, or produce cough, hæmoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hæmorrhage. Again, its pressure on the laryngeal nerves may give rise to symptoms which so accurately resemble those of laryngitis that the operation of tracheotomy has in some cases
been resorted to, from the supposition that disease existed in the larynx; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the oesophagus, producing dysphagia; or may burst into the oesophagus, when fatal hemorrhage will occur. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist or in the left temporal artery; or the tumor may present itself at or above the manubrium, generally either in the median line or to the right of the sternum, and may simulate an aneurysm of one of the arteries of the neck.

Branches of the Arch of the Aorta (Figs. 344, 345).

The branches given off from the arch of the aorta are three in number: the innominate artery, the left common carotid, and the left subclavian.

Peculiarities.—Position of the Branches.—The branches, instead of arising from the highest part of the arch (their usual position), may be moved more to the right, arising from the commencement of the transverse or upper part of the ascending portion; or the distance from one another at their origin may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid toward the innominate artery.

The Number of the primary branches may be reduced to two: the left carotid arising from the innominate artery, or (more rarely) the carotid and subclavian arteries of the left side arising from a left innominate artery. But the number may be increased to four, from the right carotid and subclavian arteries arising directly from the aorta, the innominate being absent. In most of these latter cases the right subclavian has been found to arise from the left end of the arch; in other cases it was the second or third branch given off instead of the first. Lastly, the number of trunks from the arch may be increased to five or six; in these instances the external and internal carotids arise separately from the arch, the common carotid being absent on one or both sides.

Number Usual, Arrangement Different.—When the aorta arches over to the right side, the three branches have an arrangement the reverse of what is usual, the innominate supplying the left side, and the carotid and subclavian (which arise separately) the right side. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.

Secondary Branches sometimes arise from the arch; most commonly such a secondary branch is the left vertebral, which usually takes origin between the left carotid and left subclavian, or beyond them. Sometimes, a thyroid branch is derived from the arch, or the right internal mammary, or right vertebral, or, more rarely, both vertebral.  

THE INNOMINATE ARTERY.

The innominate artery (brachio-cephalic) is the largest branch given off from the arch of the aorta. It arises opposite the fourth dorsal vertebra from the commencement of the arch of the aorta in front of the left carotid, and, ascending obliquely to the upper border of the right sterno-clavicular articulation, divides into the right common carotid and right subclavian arteries. This vessel varies from an inch and a half to two inches in length.

Relations.—In front, it is separated from the first bone of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the left innominate and right inferior thyroid veins which cross its root, and sometimes the inferior cervical cardiac branch of the right pneumogastric. Behind, it lies upon the trachea, which it crosses obliquely. On the right side is the right innominate vein, right pneumogastric nerve, and the pleura; and on the left side, the remains of the thymus gland, the origin of the left carotid artery, the left inferior thyroid vein, and the trachea.

Branches.—The innominate usually gives off no branches, but occasionally a small branch, the thyroidea ima, is given off from this vessel. It also sometimes gives off a thymic or bronchial branch. The Thyroidea ima ascends in front of the trachea to the lower part of the thyroid body, which it supplies. It varies greatly in size, and appears to compensate for deficiency or absence of one of the other thyroid vessels. It occasionally is found to arise from the subclavian or internal mammary vessel.

1 The anomalies of the aorta and its branches are minutely described by Krause in Henle's Anatomy (Brunswick, 1868), vol. iii. p. 203 et seq.

Peculiarities in Point of Division.—When the bifurcation of the innominate artery varies from the point above mentioned, it sometimes ascends a considerable distance above the sternal end of the clavicle; less frequently it divides below it. In the former class of cases its length may exceed two inches, and in the latter be reduced to an inch or less. These are points of considerable interest for the surgeon to remember in connection with the operation of tying this vessel.

Position.—When the aorta arches over to the right side, the innominate is directed to the left side of the neck instead of the right.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligation of the innominate artery, by tying and dividing that artery, after which, he says, "Even coarse injection, impelled into the aorta, passing freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely." (Surgical Anatomy of the Head and Neck, p. 62). The branches by which this circulation would be carried on are very numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides would be available for the supply of blood to the right side of the head and neck; while the anastomosis between the superior intercostal of the subclavian and the first aortic intercostal (see infra on the collateral circulation after obliteration of the thoracic aorta) would bring the blood, by a free and direct course, into the right subclavian: the numerous connections, also, between the intercostal arteries and the branches of the axillary and internal mammary arteries would, doubtless, assist in the supply of blood to the right arm, while the epigastric, from the external iliac, would, by means of its anastomosis with the internal mammary, compensate for any deficiency in the vascularity of the wall of the chest.

Surgical Anatomy.—Although the operation of tying the innominate artery has been performed by several surgeons for aneurism of the right subclavian extending inward as far as the Scalenus, in only two instances has the patient survived.¹ Mott's patient, however, on whom the operation was first performed, lived nearly four weeks, and Graebe's more than two months. The main obstacles to the operation are, as the student will perceive from his dissection of this vessel, the deep situation of the artery behind and beneath the sternum and the number of important structures which surround it in every part.

In order to apply a ligature to this vessel, the patient is to be placed upon his back, with the thorax slightly raised, the head bent a little backward, and the shoulder on the side of the aneurism strongly depressed, so as to draw out the artery from behind the sternum into the neck. An incision three or more inches long is then made along the anterior border of the Sterno-mastoïd muscle, terminating at the sternal end of the clavicle. From this point a second incision is carried about the same length along the upper border of the clavicle. The skin is then dissected back, and the Platysma divided on a director; the sternal end of the Sterno-mastoïd is now brought into view, and, a director being passed beneath it and close to its under surface, so as to avoid any small vessels, it is to be divided; in like manner the clavicular origin is to be divided throughout the whole or greater part of its attachment. By pressing aside any loose cellular tissue or vessels that may now appear the Sterno-hyoid and Sterno-thyroid muscles will be exposed, and must be divided, a director being previously passed beneath them. The inferior thyroid veins may come into view, and must be carefully drawn, either upward or downward, by means of a blunt hook, or tied with double ligatures and divided. After tearing through a strong fibro-cellular lamina, the right carotid is brought into view, and, being traced downward, the artery innominata is arrived at. The left innominate vein should now be depressed; the right innominate vein, the internal jugular vein, and the pneumogastric nerve drawn to the right side; and a curved aneurism needle may then be passed around the vessel, close to its surface, and in a direction from below upward and inward, care being taken to avoid the right pleural sac, the trachea, and cardiac nerves. The ligature should be applied to the artery as high as possible, in order to allow room between it and the aorta for the formation of the coagulum.

¹ In one of these the operation was performed by Dr. Smyth of New Orleans. See the New Sydenham Society's Biennial Retrospect for 1855–6, p. 546. In the other, the operation was performed by Dr. Mitchell Banks in the Liverpool Infirmary. The case is recorded by Mr. Jacobson in Operations of Surgery, p. 586.
THE COMMON CAROTID ARTERIES.

The importance of avoiding the thyroid plexus of veins during the primary steps of the operation, and the pleural sac whilst including the vessel in the ligature, should be most carefully borne in mind. The most frequent cause of death after operation is secondary haemorrhage, which has occurred in almost every case. Other causes are pleurisy, pericarditis, and suppulsive cellulitis.

THE COMMON CAROTID ARTERIES.

The common carotid arteries, although occupying a nearly similar position in the neck, differ in position, and, consequently, in their relation at their origin. The right carotid arises from the innominate artery, behind the right sternoclavicular articulation; the left from the highest part of the arch of the aorta. The left carotid is, consequently, longer, and at its origin is contained within the thorax. The course and relations of that portion of the left carotid which intervenes between the arch of the aorta and the left sternoclavicular articulation will first be described (see Fig. 344).

The left carotid within the thorax ascends obliquely outward from the arch of the aorta to the root of the neck. In front, it is separated from the first piece of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the left innominate vein, and the remains of the thymus gland; behind, it lies on the trachea, oesophagus, and thoracic duct. Internally, it is in relation with the innominate artery, inferior thyroid veins and remains of thymus gland; externally, with the left pneumogastric nerve, left pleura, and lung. The left subclavian artery is posterior and external to it.

In the neck the two common carotids resemble each other so closely that one description will apply to both. Each vessel passes obliquely upward from behind the sternoclavicular articulation to a level with the upper border of the thyroid cartilage, opposite the third cervical vertebra, where it divides into the external and internal carotid; these names being derived from the distribution of the arteries to the external parts of the head and face and to the internal parts of the cranium and orbit respectively.

At the lower part of the neck the two common carotid arteries are separated from each other by a small interval, which contains the trachea; but at the upper part, the thyroid body, the larynx and pharynx project forward between the two vessels, and give the appearance of their being placed farther back in that situation. The common carotid artery is contained in a sheath derived from the deep cervical fascia, which also encloses the internal jugular vein and pneumogastric nerve, the vein lying on the outer side of the artery, and the nerve between the artery and vein, on a plane posterior to both. On opening the sheath these three structures are seen to be separated from one another, each being enclosed in a separate fibrous investment.

Relations.—At the lower part of the neck the common carotid artery is very
deeply seated, being covered by the integument, superficial fascia, Platysma, and deep cervical fascia, the Sterno-mastoid, Sterno-hyoid, and Sterno-thyroid muscles, and by the Omo-hyoid, opposite the cricoid cartilage; but in the upper part of its course, near its termination, it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep cervical fascia, and inner margin of the Sterno-mastoid, and is contained in a triangular space, bounded behind by the Sterno-mastoid, above by the posterior belly of the Digastric, and below by the anterior belly of the Omo-hyoid. This part of the artery is crossed obliquely, from within outward, by the sterno-mastoid artery; it is crossed also by one, or sometimes two superior thyroid veins, which terminate in the internal jugular; and, descending on its sheath in front, is seen the descendens hypoglossi nerve, this filament being joined by one or two branches from the cervical nerves, which cross the vessel from without inward. Sometimes the descendens hypoglossi is contained within the sheath. The middle thyroid vein crosses the artery about
its middle, and the anterior jugular vein below. \textit{Behind}, the artery lies in front of the cervical portion of the spine, resting first on the Longus colli muscle, then on the Rectus capitis anticus major, from which it is separated by the sympathetic nerve. The recurrent laryngeal nerve and inferior thyroid artery cross behind the vessel at its lower part. \textit{Internally}, it is in relation with the trachea and thyroid gland, the inferior thyroid artery and recurrent laryngeal nerve being interposed: higher up, with the larynx and pharynx. On its \textit{outer side} are placed the internal jugular vein and pneumogastric nerve.

At the lower part of the neck the internal jugular vein on the right side diverges from the artery, but on the left side it approaches it, and often crosses its lower part. This is an important fact to bear in mind during the performance of any operation on the lower part of the left common carotid artery.

\textbf{Peculiarities as to Origin.}—The \textit{right} common carotid may arise above or below its usual point, the upper border of the sterno-clavicular articulation. This variation occurs in one out of about eight cases and a half, and the origin is more frequently above than below the usual point; or the artery may arise as a separate branch from the arch of the aorta or in conjunction with the left carotid. The \textit{left} common carotid varies more frequently in its origin than the right. In the majority of abnormal cases it arises with the innominate artery, or, if the innominate artery is absent, the two carotids arise usually by a single trunk. The left carotid is occasionally the first branch given off from the arch of the aorta. It rarely joins with the left subclavian, except in cases of transposition of the arch.

\textbf{Peculiarities as to Point of Division.}—The most important peculiarities of this vessel, in a surgical point of view, relate to its place of division in the neck. In the majority of abnormal cases this occurs higher than usual, the artery dividing into two branches opposite the hyoid bone, or even higher; more rarely, it occurs below its usual place, opposite the middle of the larynx or the lower border of the cricoid cartilage; and one case is related by Morgagni where the common carotid, only an inch and a half in length, divided at the root of the neck. Very rarely the common carotid ascends in the neck without any subdivision, the internal carotid being wanting; and in a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta. This peculiarity existed on both sides in some instances, on one side in others.

\textbf{Occasional Branches.}—The common carotid usually gives off no branch previous to its bifurcation; but it occasionally gives origin to the superior thyroid or its laryngeal branch, the inferior thyroid, or, more rarely, the vertebral artery.

\textbf{Surface Marking.}—The carotid arteries are overlapped throughout their entire extent by the anterior border of the Sterno-mastoid muscle, but their course does not correspond to the border of the muscle, which passes in a somewhat curved direction from the mastoid process to the sterno-clavicular joint. The course of the artery is indicated more exactly by a line drawn from the sternal end of the clavicle below, to a point midway between the angle of the jaw and the mastoid process above. That portion of the line below the level of the upper border of the thyroid cartilage would represent the course of the vessel.

\textbf{Surgical Anatomy.}—The operation of tying the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurism, or in a case of pulsating tumor of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery above and below the wounded part. But in cases of aneurism, or where one of
the branches of the common carotid is wounded in an inaccessible situation, it may be judged necessary to tie the trunk. In such cases the whole of the artery is accessible, and any part may be tied except close to either end. When the case is such as to allow of a choice being made, the lower part of the carotid should never be selected as the spot upon which to place a ligature, for not only is the artery in this situation placed very deeply in the neck, but it is covered by three layers of muscles, and, on the left side, the internal jugular vein, in the great majority of cases, passes obliquely in front of it. Neither should the upper end be selected, for here the superior thyroid vein and its tributaries would give rise to very considerable difficulty in the application of a ligature. The point most favorable for the operation is that part of the vessel which is at the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates below its usual position; if the artery be exposed at its point of bifurcation, both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the disease.

In this operation the direction of the vessel and the inner margin of the Sterno-mastoid are the chief guides to its performance. The patient should be placed on his back with the head thrown back and turned slightly to the opposite side: an incision is to be made, three inches long, in the direction of the anterior border of the Sterno-mastoid, so that the centre corresponds to the level of the cricoid cartilage: after dividing the integument, superficial fascia, and Platysma, the deep fascia must be cut through on a director, so as to avoid wounding numerous small veins that are usually found beneath. The head may now be brought forward so as to relax the parts somewhat, and the margins of the wound held asunder by retractors. The descendent hypoglossus nerve may now be exposed, and must be avoided, and, the sheath of the vessel having been raised by forceps, is to be opened to a small extent over the artery at its inner side. The internal jugular vein may present itself alternately distended and relaxed; this should be compressed both above and below, and drawn outward, in order to facilitate the operation. The aneurism needle is passed from the outside, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein or including the vagus nerve. Before the ligature is tied it should be ascertained that nothing but the artery is included in it.

**Ligature of the Common Carotid at the Lower Part of the Neck.**—This operation is sometimes required in cases of aneurism of the upper part of the carotid, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sterno-mastoid muscle, but may be done in some cases, if the aneurism is not of very large size, by an incision along the anterior border of the Sterno-mastoid, extending down to the sterno-clavicular articulation, and then retracting the muscle. The easiest and best plan, however, is to make an incision two or three inches long down the lower part of the anterior border of the Sterno-mastoid muscle, to the sterno-clavicular joint, and a second incision, starting from the termination of the first, along the upper border of the clavicle for about two inches. This incision is made through the superficial and deep fascia, and the sternal origin of the muscle exposed. This is to be divided on a director, and turned up, with the superficial structures, as a triangular flap. Some loose connective tissue is to be divided or torn through, and the outer border of the Sterno-hyoid muscle exposed. In doing this care must be taken not to wound the anterior jugular vein, which crosses the muscle to reach the external jugular or subclavian vein. The Sterno-hyoid, and with it the Sterno-thyroid, are to be drawn inward by means of a retractor, and the sheath of the vessel is exposed. This must be opened with great care on its inner or tracheal side, so as to avoid the internal jugular vein. This is especially necessary on the left side, where the artery is commonly overlapped by the vein. On the right side there is usually an interval between the artery and the vein, and not the same risk of wounding the latter.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasor's operation for the cure of an aneurism of the lower part of the vessel. Brasor's procedure consists in ligaturing the artery on the distal side of the aneurism, and in the case of the common carotid there are no branches given off from the vessel between the aneurism and the site of the ligature; hence little or no blood passes through the sac of the aneurism, and consequently it and the vessel shrinks, and a cure is effected.

**Collateral Circulation.**—After ligature of the common carotid the collateral circulation can be perfectly established, by the free communication which exists between the carotid arteries of the two sides, with the help of branches passing through the cranial, and by enlargement of the branches of the subclavian artery on the side corresponding to that on which the vessel has been tied—the chief communication outside the skull taking place between the superior and inferior thyroid arteries, and the profunda cervicis and arteria princeps cervicis of the occipital; the vertebral taking the place of the internal carotid within the cranium.

Sir A. Cooper had an opportunity of dissecting, thirteen years after the operation, the case in which he first successfully tied the common carotid (the second case in which he performed the operation). The injection, however, does not seem to have been a successful one. It showed merely that the arteries at the base of the brain (circle of Willis) were much enlarged on

---

1 Guy's Hospital Reports, i. 56.
the side of the tied artery, and that the anastomosis between the branches of the external carotid on the affected side and those of the same artery on the sound side was free, so that the external carotid was pervious throughout.

The External Carotid Artery.

The external carotid artery (Fig. 347) commences opposite the upper border of the thyroid cartilage, and taking a slightly curved course, passes upward and forward, and then inclines backward to the space between the neck of the condyle of the lower jaw and the external meatus, where it divides into the superficial temporal and internal maxillary arteries. It rapidly diminishes in size in its course up the neck, owing to the number and large size of the branches given off from it. In the child it is somewhat smaller than the internal carotid, but in the adult the two vessels are of nearly equal size. At its commencement this artery is more superficial, and placed nearer the middle line than the internal carotid, and is contained in the triangular space bounded by the Sterno-mastoid behind, the Omo-hyoid below, and the posterior belly of the Digastric and Stylo-hyoid above.

Relations.—It is covered by the skin, superficial fascia, Platysma, deep fascia, and anterior margin of the Sterno-mastoid, crossed by the hypoglossal nerve, and by the lingual and facial veins; it is afterward crossed by the Digastric and Stylo-hyoid muscles, and higher up passes deeply into the substance of the parotid gland, where it lies beneath the facial nerve and the junction of the temporal and internal maxillary veins.

Internally is the hyoid bone, wall of the pharynx, the superior laryngeal nerve, and higher up it is separated from the internal carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, and part of the parotid gland. Anteriorly is the ramus of the jaw, from which it is separated by a portion of the parotid gland. Externally, in the lower part of its course, is the internal carotid artery.

Surface Marking.—The position of the external carotid artery may be marked out with sufficient accuracy by a line drawn from the front of the meatus of the external ear to the side of the cricoid cartilage, slightly arching the line forward.

Surgical Anatomy.—The application of a ligature to the external carotid may be required in case of wounds of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumour of the scalp or face. The operation has not received the attention which it deserves, owing to the fear which surgeons have entertained of secondary haemorrhage, on account of the number of branches given off from the vessel. This fear, however, has been shown by Mr. Cripps not to be well founded. To tie this vessel near its origin, below the point where it is crossed by the Digastric, an incision about three inches in length should be made along the margin of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The ligature should be applied between the lingual and superior thyroid branches. To tie the vessel above the Digastric, between it and the parotid gland, an incision should be made, from the lobe of the ear to the great cornu of the os hyoides, dividing successively the skin, Platysma, and fascia. By drawing the Sterno-mastoid outward, and the posterior belly of the Digastric and Stylo-hyoid muscles downward, and separating them from the parotid gland, the vessel will be exposed, and a ligature may be applied to it. The circulation is at once re-established by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid, and of the occipital with the branches of the subclavian, etc.

Plan of the Relations of the External Carotid.

Parotid gland with facial nerve and temporo-maxillary vein in its substance.
Internal carotid artery.

Branches.—The external carotid artery gives off eight branches, which, for convenience of description, may be divided into four sets. (See Fig. 348, Plan of the Branches).

- **Anterior.**
  - Superior Thyroid
  - Occipital
  - Lingual
  - Facial

- **Posterior.**
  - Ascending Pharyngeal
  - Posterior Auricular

- **Ascending.**
  - Superficial Temporal
  - Internal Maxillary

- **Terminal.**
  - Hyoid bone
  - Pharynx
  - Superior laryngeal nerve
  - Stylo-glossus
  - Stylo-pharyngeus
  - Glosso-pharyngeal nerve
  - Parotid gland

The student is here reminded that many variations are met with in the number, origin, and course of these branches in different subjects; but the above arrangement is that which is found in the great majority of cases.

The **Superior Thyroid Artery** (Figs. 347 and 352) is the first branch given off from the external carotid, being derived from that vessel just below the great cornu of the hyoid bone. At its commencement it is quite superficial, being covered by the integument, fascia, and Platysma, and is contained in the triangular space bounded by the Sterno-mastoid, Digastric, and Omo-hyoid muscles. After running upward and inward for a short distance, it curves downward and forward, in an arched and tortuous manner, to the upper part of the thyroid gland, passing beneath the Omo-hyoid, Sterno-hyoid, and Sterno-thyroid muscles, and distributes numerous branches to the anterior surface of the gland, anastomosing with its fellow of the opposite side and with the inferior thyroid arteries. Besides the arteries distributed to the muscles by which it is covered and the substance of the gland, the branches of the superior thyroid are the following:

- Hyoid
- Superficial descending branch (Sterno-mastoid)
- Superior Laryngeal
- Crico-thyroid

The **hyoid** is a small branch which runs along the lower border of the os hyoides beneath the Thyro-hyoid muscle; after supplying the muscles connected to that bone it forms an arch, by anastomosing with the vessels of the opposite side.

The **superficial descending branch** runs downward and outward across the sheath of the common carotid artery, and supplies the Sterno-mastoid and neighboring muscles and integument. There is also a distinct branch from the external carotid distributed to the Sterno-mastoid muscle.

The **superior laryngeal**, larger than either of the preceding, accompanies the superior laryngeal nerve, beneath the Thyro-hyoid muscle: it pierces the thyro-hyoid membrane, and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing with the branch from the opposite side.

The **crico-thyroid** is a small branch which runs transversely across the crico-thyroid membrane, communicating with the artery of the opposite side.

**Surgical Anatomy.**—The superior thyroid, or some of its branches, is often divided in cases of ext. throat, giving rise to considerable hemorrhage. In such cases the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the position of the artery being very superficial, and the only structures of importance covering it being a few small veins. The operation of tying the superior thyroid artery in bronchocele has been performed in numerous instances with partial or temporary success. When,
however, the collateral circulation between this vessel and the artery of the opposite side, and the inferior thyroid, is completely re-established, the tumor usually regains its former size.

The position of the superficial descending branch is of importance in connection with the operation of ligature of the common carotid artery. It crosses and lies on the sheath of this vessel, and may chance to be wounded in opening the sheath. The position of the e rico-thyroid branch should be remembered, as it may prove the source of troublesome haemorrhage during the operation of laryngotomy.

The Lingual Artery (Fig. 352) arises from the external carotid between the superior thyroid and facial; it runs obliquely upward and inward to the great cornu of the hyoid bone, then passes horizontally forward parallel with the great cornu, and, ascending perpendicularly to the under surface of the tongue, turns forward on its under surface as far as the tip of that organ, under the name of the ranine artery.

Relations.—Its first, or oblique, portion is superficial, being contained in the triangular space already described, resting upon the middle constrictor of the pharynx, and covered by the Platysma and fascia of the neck. Its second, or horizontal, portion also lies upon the middle constrictor, being covered at first by the tendon of the Digastric and the Stylo-hyoid muscle, and afterward by the H y o-glossus, the latter muscle separating it from the hypoglossal nerve. Its third, or ascending, portion lies between the Hy o-glossus and Genio-hy o-glossus muscles. The fourth, or terminal, part, under the name of the ranine, runs along the under surface of the tongue to its tip: it is very superficial, being covered only by the mucous membrane, and rests on the Lingualis on the outer side of the Genio hyo-glossus. The hypoglossal nerve crosses the lingual artery, and then becomes separated from it, in the second part of its course, by the Hy o-glossus muscle.

The branches of the lingual artery are—the

Hyoid. Sublingual.
Dorsalis Linguae. Ranine.

The hyoid branch runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The dorsalis linguae (Fig. 352) arises from the lingual artery beneath the Hy o-glossus muscle (which, in the figure, has been partly cut away to show the vessel); ascending to the dorsum of the tongue, it supplies the mucous membrane, the tonsil, soft palate, and epiglottis, anastomosing with its fellow from the opposite side.

The sublingual, which may be described as a branch of bifurcation of the lingual artery, arises at the anterior margin of the Hy o-glossus muscle, and runs forward between the Genio-hy o-glossus and the sublingual gland. It supplies the substance of the gland, giving branches to the Mylo-hyoid and neighboring muscles, the mucous membrane of the mouth and gums. One branch runs behind the alveolar process of the lower jaw in the substance of the gum to anastomose with a similar artery from the other side.

The ranine may be regarded as the other branch of bifurcation, or, as is more usual, as the continuation of the lingual artery; it runs along the under surface of the tongue, resting on the Inferior lingualis, and covered by the mucous membrane of the mouth; it lies on the outer side of the Genio-hy o-glossus, accompanied by the lingual nerve. On arriving at the tip of the tongue it has been said to anastomose with the artery of the opposite side, but this is denied by Hyrtl. These vessels in the mouth are placed one on each side of the frenum.

Surgical Anatomy.—The lingual artery may be divided near its origin in cases of cut throat, a complication that not unfrequently happens in this class of wounds; or severe haemorrhage which cannot be restrained by ordinary means may ensue from a wound or deep ulcer of the tongue. In the former case the primary wound may be enlarged if necessary, and the bleeding vessels secured. In the latter case it has been suggested that the lingual artery should be tied near its origin. Ligature of the lingual artery is also occasionally practised, as a palliative measure, in cases of cancer of the tongue, in order to check the progress of the disease by starving the growth, and it is sometimes tied as a preliminary measure to removal of
the tongue. The operation is a difficult one, on account of the depth of the artery, the number of important parts by which it is surrounded, the loose and yielding nature of the parts upon which it is supported, and its occasional irregularity of origin. An incision is to be made in a curved direction from a finger's breadth external to the symphysis of the jaw downward to the cornu of the hyoid bone, and then upward to near the angle of the jaw. Care must be taken not to carry this incision too far backward, for fear of endangering the facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia exposed. This is then to be incised and the submaxillary gland exposed and pulled upward by retractors. A triangular space is now exposed, bounded internally by the posterior border of the Mylo-hyoid muscle; below and externally, by the tendon of the Digastric; and above, by the hypo-glossal nerve. The floor of the space is formed by the Hyo-glossus muscle, beneath which the artery lies. The fibres of this muscle are now to be cut through horizontally and the vessel exposed, care being taken, while near the vessel, not to open the pharynx. Troublesome haemorrhage may occur in the division of the frenum in children if the ranine artery, which lies on each side of it, is wounded. The student should remember that the operation is always to be performed with a pair of blunt-pointed scissors, and the mucous membrane only is to be divided by a very superficial cut, which cannot endanger any vessel. The scissors, also, should be directed away from the tongue. Any further liberation of the tongue which may be necessary can be effected by tearing.

The Facial Artery (Fig. 349) arises a little above the lingual, and passes obliquely upward, beneath the Digastric and Stylo-hyoid muscles; it then runs forward under cover of the body of the lower jaw, lodged in a groove on the posterior surface of the submaxillary gland; this may be called the cervical part of the artery. It then curves upward over the body of the jaw at the anterior inferior angle of the Masseter muscle; passes forward and upward across the

![Fig. 349.—The arteries of the face and scalp.](image)

1 The muscular tissue of the lips must be supposed to have been cut away, in order to show the course of the coronary arteries.
BRANCHES OF THE EXTERNAL CAROTID. 555

cheek to the angle of the mouth, then upward along the side of the nose, and terminates at the inner canthus of the eye, under the name of the angular artery. This vessel, both in the neck and on the face, is remarkably tortuous: in the former situation, to accommodate itself to the movements of the pharynx in deglutition, and in the latter to the movements of the jaw and the lips and cheeks.

Relations.—In the neck its origin is superficial, being covered by the integument, Platysma, and fascia; it then passes beneath the Digastric and Stylohyoid muscles and the submaxillary gland. On the face, where it passes over the body of the lower jaw, it is comparatively superficial, lying immediately beneath the Platysma. In this situation its pulsation may be distinctly felt, and compression of the vessel effectually made against the bone. In its course over the face it is covered by the integument, the fat of the cheek, and, near the angle of the mouth, by the Platysma, Risorius, and Zygomatic muscles. It rests on the Buccinator, the Levator anguli oris, and the Levator labii superioris (sometimes piercing or else passing under this last muscle). It is accompanied by the facial vein throughout its entire course; the vein is not tortuous like the artery, and, on the face, is separated from that vessel by a considerable interval, lying to its outer side. The branches of the facial nerve cross the artery, and the infra-orbital nerve lies beneath it.

The branches of this vessel may be divided into two sets: those given off below the jaw (cervical), and those on the face (facial).

Cervical Branches. Facial Branches.
Inferior or Ascending Palatine. Muscular.
Tonsillar. Inferior Labial.
Submaxillary. Inferior Coronary.
Submental. Superior Coronary.
Muscular. Lateralis Nasi.
Angular.

The inferior or ascending palatine (Fig. 352) passes up between the Styloglossus and Stylo-pharyngeus to the outer side of the pharynx. After supplying these muscles, the tonsil, and Eustachian tube, it divides, near the Levator palati, into two branches: one follows the course of the Levator palati, and, winding over the upper border of the Superior constrictor, supplies the soft palate and the palatine glands; the other pierces the Superior constrictor, supplies the tonsil, anastomosing with the tonsillar artery. These vessels also anastomose with the posterior palatine branch of the internal maxillary artery.

The tonsillar branch (Fig. 352) passes up between the Internal Pterygoid and Stylo-glossus, and then ascends along the side of the pharynx, perforating the Superior constrictor, to ramify in the substance of the tonsil and root of the tongue.

The submaxillary consists of three or four large branches, which supply the submaxillary gland, some being prolonged to the neighboring muscles, lymphatic glands, and integument.

The submental, the largest of the cervical branches, is given off from the facial artery just as that vessel quits the submaxillary gland: it runs forward upon the Mylo-hyoid muscle, just below the body of the jaw and beneath the Digastric; after supplying the surrounding muscles, and anastomosing with the sublingual artery by branches which perforate the Mylo-hyoid muscle, it arrives at the symphysis of the chin, where it turns over the border of the jaw and divides into a superficial and a deep branch; the former passes between the integument and Depressor labii inferioris, supplies both, and anastomoses with the inferior labial. The deep branch passes between the latter muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The muscular branches are distributed to the Internal pterygoid and Stylo-hyoid in the neck, and to the Masseter and Buccinator on the face.

The inferior labial passes beneath the Depressor anguli oris, to supply the
muscles and integument of the lower lip, anastomosing with the inferior coronary and submental branches of the facial, and with the mental branch of the inferior dental artery.

The inferior coronary is derived from the facial artery, near the angle of the mouth: it passes upward and inward beneath the depressor anguli oris, and, penetrating the Orbicularis oris muscle, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane, inosculating with the artery of the opposite side. This artery supplies the labial glands, the mucous membrane, and muscles of the lower lip, and anastomoses with the inferior labial and the mental branch of the inferior dental artery.

The superior coronary is larger and more tortuous in its course than the preceding. It follows the same course along the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the textures of the upper lip, and gives off in its course two or three vessels which ascend to the nose. One, named the inferior artery of the septum, ramifies on the septum of the nares as far as the point of the nose; another, the artery of the ala, supplies the ala of the nose.

The lateralis nasi is derived from the facial, as that vessel is ascending along the side of the nose; it supplies the ala and dorsum of the nose, anastomosing with its fellow, the nasal branch of the ophthalmic, the inferior artery of the septum, the artery of the ala, and the infra-orbital.

The angular artery is the termination of the trunk of the facial; it ascends to the inner angle of the orbit, imbedded in the fibres of the Levator labii superioris alæque nasi, and accompanied by a large vein, the angular; it distributes some branches on the cheek which anastomose with the infra-orbital, and after supplying the lachrymal sac and Orbicularis palpebrarum muscle, terminates by anastomosing with the nasal branch of the ophthalmic artery.

The anastomoses of the facial artery are very numerous, not only with the vessel of the opposite side, but, in the neck, with the sublingual branch of the lingual; with the ascending pharyngeal; with the posterior palatine, a branch of the internal maxillary, by its inferior or ascending palatine and tonsillar branches; on the face, with the mental branch of the inferior dental as it emerges from the mental foramen, with the transverse facial, a branch of the temporal; with the infra-orbital, a branch of the internal maxillary, and with the nasal branch of the ophthalmic.

Peculiarities.—The facial artery not unfrequently arises by a common trunk with the lingual. This vessel is also subject to some variations in its size and in the extent to which it supplies the face. It occasionally terminates as the submental, and not unfrequently supplies the face only as high as the angle of the mouth or nose. The deficiency is then supplied by enlargement of one of the neighboring arteries.

Surgical Anatomy.—The passage of the facial artery over the body of the jaw would appear to afford a favorable position for the application of pressure in case of hemorrhage from the lips, the result either of an accidental wound or during an operation; but its application is useless, except for a very short time, on account of the free communication of this vessel with its fellow and with numerous branches from different sources. In a wound involving the lip it is better to seize the part between the fingers, and exert it, when the bleeding vessel may be at once secured with pressure-forceps. In order to prevent hemorrhage in cases of removal of diseased growths from the part, the lip should be compressed on each side between the fingers and thumb or by a pair of specially devised clamp-forceps, whilst the surgeon excises the diseased part. In order to stop hemorrhage where the lip has been divided in an operation, it is necessary, in unifying the edges of the wound, to pass the sutures through the cut edges, almost as deep as its mucous surface; by these means not only are the cut surfaces more nearly and securely adapted to each other, but the possibility of hemorrhage is prevented by including in the suture the divided artery. If the suture is, on the contrary, passed through merely the cutaneous portion of the wound, hemorrhage occurs into the cavity of the mouth. The student should, lastly, observe the relation of the angular artery to the lachrymal sac, and it will be seen that, as the vessel passes up along the inner margin of the orbit, it ascends on its nasal side. In operating for fistula lachrymalis the sac should always be opened on its outer side, in order that this vessel may be avoided.

The Occipital Artery (Fig. 849) arises from the posterior part of the external carotid, opposite the facial near the lower margin of the Digastric muscle. At its origin it is covered by the posterior belly of the Digastric and Stylo-hyoid muscles,
BRANCHES OF THE EXTERNAL CAROTID.

and the hypoglossal nerve winds around it from behind forward; higher up, it passes across the internal carotid artery, the internal jugular vein, and the pneumogastric and spinal accessory nerves; it then ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backward, grooving the surface of the latter bone, being covered by the Sterno-mastoid, Splenius, Trachelo-mastoid, and Digastric muscles, and resting upon the Rectus lateralis, the Superior oblique, and Complexus muscles; it then changes its course and passes vertically upward, pierces the fascia which connects the cranial attachment of the Trapezius with the Sterno-mastoid, and ascends in a tortuous course over the occiput, as high as the vertex, where it divides into numerous branches. It is accompanied in the latter part of its course by the great occipital and a cutaneous filament from the suboccipital nerve.

The branches given off from this vessel are—

---|---|---
Sterno-mastoid. | Arteria Princeps Cervicis.

The Muscular branches supply the Digastric, Stylo-hyoid, Splenius, and Trachelo-mastoid muscles.

The sterno-mastoid is a large and constant branch, generally arising from the artery close to its commencement. It first passes upward and backward, and then turns downward over the hypoglossal nerve, and enters the substance of the muscle, frequently in company with the spinal accessory nerve.

The auricular branch supplies the back part of the concha. It frequently gives off a branch, which enters the skull through the mastoid foramen and supplies the dura mater.

The meningeal branch ascends with the internal jugular vein, and enters the skull through the foramen lacerum posterius, to supply the dura mater in the posterior fossa.

The Arteria princeps cervicis (Fig. 352) is a large branch which descends along the back part of the neck and divides into a superficial and deep branch. The former runs beneath the Splenius, giving off branches which perforate that muscle to supply the Trapezius which anastomose with the superficial cervical artery, a branch of the transversalis colli: the latter passes beneath the Complexus between it and the Semispinalis colli, and anastomoses with branches from the vertebral and with the deep cervical artery, a branch of the superior intercostal. The anastomosis between these vessels serves mainly to establish the collateral circulation after ligature of the carotid or subclavian artery.

The cranial branches of the occipital artery are distributed upon the occiput; they are very tortuous, and lie between the integument and Occipito-frontalis, anastomosing with the artery of the opposite side, the posterior auricular and temporal arteries. They supply the back part of the Occipito-frontalis muscle, the integument, and pericranium.

The Posterior Auricular Artery (Fig. 349) is a small vessel which arises from the external carotid, above the Digastric and Stylo-hyoid muscles, opposite the apex of the styloid process. It ascends, under cover of the parotid gland, to the groove between the cartilage of the ear and the mastoid process, immediately above which it divides into two branches: an anterior, auricular, passing forward to supply the back of the auricle and anastomose with the posterior division of the temporal; and a posterior, mastoid, to the scalp above and behind the ear, communicating with the occipital. Just before arriving at the mastoid process this artery is crossed by the facial nerve, and has beneath it the spinal accessory nerve.

Besides several small branches to the Digastric, Stylo-hyoid, and Sterno-mastoid muscles and to the parotid gland, this vessel gives off three branches:

The stylo-mastoid branch enters the stylo-mastoid foramen, and supplies the
tympanum, mastoid cells, and semicircular canals. In the young subject a branch from this vessel forms, with the tympanic branch from the internal maxillary, a vascular circle, which surrounds the auditory meatus, and from which delicate vessels ramify on the membrana tympani. It anastomoses with the petrosal branch of the middle meningeal artery by a twig which enters the hiatus Fallopian.

The **auricular branch** is distributed to the back part of the cartilage of the ear, upon which it ramifies minutely, some branches curving round the margin of the fibro-cartilage, others perforating it, to supply its anterior surface. It anastomoses with the anterior auricular branches of the temporal.

The **mastoid branch** passes backward, over the Sterno-mastoid muscle, to the scalp above and behind the ear. It supplies the posterior belly of the Occipito-frontalis muscle and the scalp in this situation. It anastomoses with the occipital artery.

The **Ascending Pharyngeal Artery** (Fig. 352), the smallest branch of the external carotid, is a long, slender vessel, deeply seated in the neck, beneath the other branches of the external carotid and the Stylo-pharyngeus muscle. It arises from the back part of the external carotid, near the commencement of that vessel, and ascends vertically between the internal carotid and the side of the pharynx, to the under surface of the base of the skull, lying on the Rectus capitis anticus major. Its branches may be subdivided into three sets:

- Prevertebral.
- Pharyngeal.
- Meningeal.

The **prevertebral branches** are numerous small vessels which supply the Recti capitis antici and Longus colli muscles, the sympathetic, hypoglossal, and pneumogastric nerves, and the lymphatic glands of the neck, anastomosing with the ascending cervical artery.

The **pharyngeal branches** are three or four in number. Two of these descend to supply the middle and inferior Constrictors and the Stylo-pharyngeus, ramifying in their substance and in the mucous membrane lining them. The largest of the pharyngeal branches passes inward, running upon the Superior constrictor, and sends ramifications to the soft palate and tonsil, which take the place of the ascending palatine branch of the facial artery when that vessel is of small size. A twig from this branch passes up the Eustachian tube to supply the tympanum.

The **meningeal branches** consist of several small vessels, which pass through foramina in the base of the skull, to supply the dura mater. One, the posterior meningeal, enters the cranium through the foramen lacerum posterior; a second passes through the foramen lacerum medium; and occasionally a third through the anterior condyloid foramen. They are all distributed to the dura mater.

**Surgical Anatomy.**—The ascending pharyngeal artery has been wounded from the throat, as in the case in which the stem of a tobacco-pipe was driven into the vessel, causing fatal haemorrhage.

The **Superficial Temporal Artery** (Fig. 349), the smaller of the two terminal branches of the external carotid, appears, from its direction, to be the continuation of that vessel. It commences in the substance of the parotid gland, in the interspace between the neck of the condyle of the lower jaw and the external meatus, crosses over the posterior root of the zygoma, passes beneath the Attra-hens aurum muscle, and divides, about two inches above the zygomatic arch, into two branches, an anterior and a posterior.

The **anterior temporal** inclines forward over the forehead, supplying the muscles, integument, and pericranium in this region, and anastomoses with the supra-orbital and frontal arteries.

The **posterior temporal**, larger than the anterior, curves upward and backward along the side of the head, lying superficial to the temporal fascia, and inosculates with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

The superficial temporal artery, as it crosses the zygoma, is covered by the Attra-hens aurum muscle and by a dense fascia given off from the parotid gland; it is usually crossed by one or two veins, and accompanied by branches of the
facial and auriculo-temporal nerves. Besides some twigs to the parotid gland, the articulation of the jaw, and the Masseter muscle, its branches are—the

Transverse Facial. Middle Temporal. Anterior Auricular.

The transverse facial is given off from the temporal before that vessel quits the parotid gland; running forward through its substance, it passes transversely across the face, between Stenson's duct and the lower border of the zygoma, and divides on the side of the face into numerous branches, which supply the parotid gland, the Masseter muscle, and the integument, anastomosing with the facial, masseteric, and infra-orbital arteries. This vessel rests on the Masseter, and is accompanied by one or two branches of the facial nerve. It is sometimes a branch of the external carotid.

The middle temporal artery arises immediately above the zygomatic arch, and, perforating the temporal fascia, supplies the Temporal muscle, anastomosing with the deep temporal branches of the internal maxillary. It occasionally gives off an orbital branch, which runs along the upper border of the zygoma, between the two layers of the temporal fascia, to the outer angle of the orbit. This branch supplies the Orbicularis palpebrarum, and anastomoses with the lachrymal and palpebral branches of the ophthalmic artery.

The anterior auricular branches are distributed to the anterior portion of the pinna, the lobule, and part of the external meatus, anastomosing with branches of the posterior auricular.

Surgical Anatomy.—It occasionally happens that the surgeon is called upon to perform the operation of arteriotomy upon this vessel in cases of inflammation of the eye or brain. If the student will consider the relations of the trunk of this vessel as it crosses the zygomatic arch with the surrounding structures, he will observe that it is covered by a thick and dense fascia, crossed by one or two veins, and accompanied by branches of the facial and auriculo-temporal nerves. Bleeding should not be performed in this situation, as much difficulty may arise from the dense fascia over the vessel preventing a free flow of blood, and considerable pressure is requisite afterward to repress the hemorrhage. Again, a varicose aneurism may be formed by the accidental opening of one of the veins in front of the artery, or severe neuralgic pain may arise from the operation implicating one of the nervous filaments in the neighborhood. The anterior branch, on the contrary, is subcutaneous, is a large vessel, and is readily compressed; it should consequently always be selected for the operation.

The Internal Maxillary (Fig. 350), the larger of the two terminal branches of the external carotid, passes inward, at right angles from that vessel, to the inner side of the neck of the condyle of the lower jaw, to supply the deep structures of the face. At its origin, it is imbedded in the substance of the parotid gland, being on a level with the lower extremity of the lobule of the ear.

In the first part of its course (maxillary portion) the artery passes horizontally forward and inward, between the ramus of the jaw and the internal lateral ligament. The artery here lies parallel with the auriculo-temporal nerve; it crosses the inferior dental nerve, and lies along the lower border of the External pterygoid muscle.

In the second part of its course (pterygoid portion) it runs obliquely forward and upward upon the outer surface of the External pterygoid muscle, being covered by the ramus of the lower jaw and lower part of the Temporal muscle.

In the third part of its course (sphen-maxillary portion) it approaches the superior maxillary bone, and enters the sphen-maxillary fossa in the interval between the two heads of the External pterygoid, where it lies in relation with Meckel's ganglion, and gives off its terminal branches.

Peculiarities.—Occasionally, this artery passes between the two Pterygoid muscles. The vessel in this case passes forward to the interval between the processes of origin of the External pterygoid, in order to reach the superior maxillary bone. Sometimes the vessel escapes from beneath the External pterygoid by perforating the middle of that muscle.

The branches of this vessel may be divided into three groups, corresponding with its three divisions.
Branches of the First or Maxillary Portion of the Internal Maxillary (Fig. 351).

Tympanic (anterior).  
Small Meningeal.  
Middle Meningeal.  
Inferior Dental.  

The tympanic branch passes upward behind the articulation of the lower jaw, enters the tympanum through the Glaserian fissure, and ramifies upon the mem-

![Diagram of the internal maxillary artery and its branches.](image)

Fig. 350.—The internal maxillary artery, and its branches.

brana tympani, forming a vascular circle around the membrane with the stylo-

mastoid artery, and anastomosing with the Vidian and the tympanic branch from

the internal carotid. It gives off a branch (deep auricular) to the external meatus, supplying its lining and the outer surface of the membrana tympani.

The middle meningeal is the largest of the branches which supply the dura mater. It arises from the internal maxillary, between the internal lateral liga-

cent and the neck of the jaw, and passes vertically upward between the two

roots of the auriculo-temporal nerve to the foramen spinosum of the sphenoid

bone. On entering the cranium it divides into two branches, anterior and poste-

rior. The anterior branch, the larger, crosses the great ala of the sphenoid, and

reaches the groove, or canal, in the anterior inferior angle of the parietal bone: it

then divides into branches which spread out between the dura mater and internal

surface of the cranium, some passing upward over the parietal bone as far as the

vertex, and others backward to the occipital bone. The posterior branch crosses

the squamous portion of the temporal, and on the inner surface of the parietal

![Diagram of the plan of the branches.](image)

Fig. 351.—Plan of the branches.
bone divides into branches which supply the posterior part of the dura mater and cranium. The branches of this vessel are distributed partly to the dura mater, but chiefly to the bones; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal.

The middle meningeal on entering the cranium gives off the following collateral branches: 1. Numerous small vessels to the ganglion of the fifth nerve and to the dura mater in this situation; 2. A branch (petrosal branch), which enters the hiatus Fallopii, supplies the facial nerve, and anastomoses with the stylo-mastoid branch of the posterior auricular artery; 3. Orbital branches, which pass through the sphenoidal fissure or through separate canals in the great wing of the sphenoid to anastomose with the lacrimal or other branches of the ophthalmic artery; 4. Temporal branches, which pass through foramina in the great wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries.

**Surgical Anatomy.**—The middle meningeal is an artery of considerable surgical importance, as it may be injured in fractures of the temporal region of the skull, and the injury may be followed by considerable haemorrhage between the bone and dura mater, which may cause compression of the brain and require the operation of trephining for its relief. This artery crosses the anterior inferior angle of the parietal bone at a point 1 1/2 inches behind the external angular process of the frontal bone, and 1 1/2 inches above the zygoma. From this point the anterior branch passes upward and slightly backward to the sagittal suture, lying about 1 inch to 1/2 inch behind the coronal suture. The posterior branch passes upward and backward over the squamous portion of the temporal bone. In order to expose the artery as it lies in the canal in the parietal bone, a semilunar incision, with its convexity upward, should be made, commencing an inch behind the external angular process, and carried backward for 2 inches. The structures cut through are: (1) skin; (2) superficial fascia, with branches of the superficial temporal vessels and nerves; (3) the fascia continued down from the aponeurosis of the Occipito-frontalis; (4) the two layers of the temporal fascia; (5) the temporal muscle; (6) the deep temporal vessels; (7) the perieranium; and (8) the bone.

The small meningeal is sometimes derived from the preceding. It enters the skull through the foramen ovale, and supplies the Gasserian ganglion and dura mater. Before entering the cranium it gives off a branch to the nasal fossa, soft palate, and tonsil.

The inferior dental descends with the dental nerve to the foramen on the inner side of the ramus of the jaw. It runs along the dental canal in the substance of the bone, accompanied by the nerve, and opposite the first bicuspid tooth divides into two branches, incisor and mental; the former is continued forward beneath the incisor teeth as far as the symphysis, where it anastomoses with the artery of the opposite side; the mental branch escapes with the nerve at the mental foramen, supplies the structures composing the chin, and anastomoses with the submental, inferior labial, and inferior coronary arteries. As the dental artery enters the foramen it gives off a mylo-hyoid branch, which runs in the mylo-hyoid groove, and ramifies on the under surface of the Mylo-hyoid muscle. The dental and incisor arteries during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth: these enter the minute apertures at the extremities of the fangs and supply the pulp of the teeth.

**Branches of the Second or Pterygoid Portion of Internal Maxillary.**

- Deep Temporal.
- Pterygoid.
- Masseteric.
- Buccal.

These branches are distributed, as their names imply, to the muscles in the maxillary region.

The deep temporal arteries, two in number, anterior and posterior, each occupy that part of the temporal fossa indicated by its name. Ascending between the Temporal muscle and perieranium, they supply that muscle and anastomose with the other temporal arteries, the anterior branch communicating with the lacrimal through small branches which perforate the malar bone and great wing of the sphenoid.
The **pterogoid branches**, irregular in their number and origin, supply the Pterygoid muscles.

The **masseteric** is a small branch which passes outward, above the sigmoid notch of the lower jaw, to the deep surface of the Masseter. It supplies that muscle, and anastomoses with the masseteric branches of the facial and with the transverse facial artery.

The **buccal** is a small branch which runs obliquely forward between the Internal pterygoid and the ramus of the jaw, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the facial artery.

### Branches of the Third or Spheno-maxillary Portion of Internal Maxillary.

- **Alveolar.**
- **Infra-orbital.**
- **Posterior or Descending Palatine.**
- **Vidian.**
- **Pterygo-palatine.**
- **Naso- or Spheno-palatine.**

The **alveolar** or **posterior dental branch** is given off from the internal maxillary by a common branch with the infra-orbital, and just as the trunk of the vessel is passing into the sphenomaxillary fossa. Descending upon the tuberosity of the superior maxillary bone, it divides into numerous branches, some of which enter the posterior dental canals, to supply the molar and bicuspids teeth and the lining of the antrum, and others are continued forward on the alveolar process to supply the gums.

The **infra-orbital** appears, from its direction, to be the continuation of the trunk of the internal maxillary. It arises from that vessel by a common trunk with the preceding branch, and runs along the infra-orbital canal with the superior maxillary nerve, emerging upon the face at the infra-orbital foramen, beneath the Levator labii superioris. Whilst contained in the canal, it gives off branches which ascend into the orbit, and supply the Inferior rectus and Inferior oblique muscles and the lachrymal gland. Other branches (anterior dental) descend through canals in the bone to supply the mucus membrane of the antrum and the front teeth of the upper jaw. On the face some branches pass inward toward the nose, anastomosing with the angular branch of the facial artery and nasal branch of the ophthalmic; and other branches descend beneath the Levator labii superioris and anastomose with the transverse facial and buccal branches.

The four remaining branches arise from that portion of the internal maxillary which is contained in the sphenomaxillary fossa.

The **descending palatine** passes down the posterior palatine canal with the anterior palatine branch of Meckel’s ganglion, and, emerging from the posterior palatine foramen, runs forward in a groove on the inner side of the alveolar border of the hard palate to the anterior palatine canal, where the terminal branch of the artery passes upward through the foramen of Stenson to anastomose with the naso-palatine artery. Its branches are distributed to the gums, the mucus membrane of the hard palate, and the palatine glands. Whilst it is contained in the palatine canal it gives off branches, which descend in the accessory palatine canals to supply the soft palate and tonsil, anastomosing with the ascending palatine artery.

The **Vidian branch** passes backward along the Vidian canal with the Vidian nerve. It is distributed to the upper part of the pharynx and Eustachian tube, sending a small branch into the tympanum, which anastomoses with the anterior tympanic.

The **pterygo-palatine** is also a very small branch, which passes backward through the pterygo-palatine canal with the pharyngeal nerve, and is distributed to the upper part of the pharynx and Eustachian tube.

The **spheno-palatine** passes through the sphenopalatine foramen into the cavity of the nose, at the back part of the superior meatus, and divides into two branches: one internal, the naso-palatine or superior artery of the septum, passes
obliquely downward and forward along the septum nasi, supplies the mucous membrane, and anastomoses in front with the terminal branch of the descending palatine. The external branches, two or three in number, supply the mucous membrane covering the lateral wall of the nose, the antrum, and the ethmoid and sphenoid cells.

SURGICAL ANATOMY OF THE TRIANGLES OF THE NECK.

The student having considered the relative anatomy of the large arteries of the neck and their branches, and the relations they bear to the veins and nerves, should now examine these structures collectively, as they present themselves in certain regions of the neck, in each of which important operations are constantly being performed.

The side of the neck presents a somewhat quadrilateral outline, limited, above, by the lower border of the body of the jaw, and an imaginary line extending from the angle of the jaw to the mastoid process; below, by the prominent upper border of the clavicle; in front, by the median line of the neck; behind, by the anterior margin of the Trapezius muscle. This space is subdivided into two large triangles by the Sterno-mastoid muscle, which passes obliquely across the neck, from the sternum and clavicle below to the mastoid process above. The triangular space in front of this muscle is called the anterior triangle; and that behind it, the posterior triangle.

ANTERIOR TRIANGLE OF THE NECK.

The anterior triangle is bounded, in front, by a line extending from the chin to the sternum; behind, by the anterior margin of the Sterno-mastoid; its base, directed upward, is formed by the lower border of the body of the jaw and a line extending from the angle of the jaw to the mastoid process; its apex is below, at the sternum. This space is subdivided into three smaller triangles by the Digastric muscle above and the anterior belly of the Omo-hyoid below. These smaller triangles are named, from below upward, the inferior carotid, the superior carotid, and the submaxillary triangle.

The Inferior Carotid Triangle is bounded, in front, by the median line of the neck; behind, by the anterior margin of the Sterno-mastoid; above, by the anterior belly of the Omo-hyoid; and is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which is the descending branch of the superficialis colli nerve. Beneath these superficial structures are the Sterno-hyoid and Sterno-thyroid muscles, which, together with the anterior margin of the Sterno-mastoid, conceal the lower part of the common carotid artery.1

This vessel is enclosed within its sheath, together with the internal jugular vein and pneumogastric nerve; the vein lying on the outer side of the artery on the right side of the neck, but overlapping it, or passing directly across it on the left side; the nerve lying between the artery and vein, on a plane posterior to both. In front of the sheath are a few filaments descending from the loop of communication between the descendens and communicans hypoglossi; behind the sheath are seen the inferior thyroid artery, the recurrent laryngeal nerve, and the sympathetic nerve; and on its inner side, the trachea, the thyroid gland—much more prominent in the female than in the male—and the lower part of the larynx. By cutting into the upper part of this space and slightly displacing the Sterno-mastoid muscle the common carotid artery may be tied below the Omo-hyoid muscle.

The floor of the inferior carotid triangle is formed by the Longus colli muscle below, by the Scaleni anticus above (see Fig. 284, page 424), between which

1 Therefore the common carotid artery and internal jugular vein are not, strictly speaking, contained in this triangle, since they are covered by the Sterno-mastoid muscle; that is to say, lie behind the anterior border of that muscle, which forms the posterior border of the triangle. But as they lie very close to the structures which are really contained in the triangle, and whose position it is essential to remember in operating on this part of the artery, it has seemed expedient to study the relations of all these parts together.
THE ARTERIES.

muscles the vertebral artery and vein will be found passing into the foramen in the sixth transverse process; a small portion of the origin of the Rectus capitis anticus major may also be seen in the floor of the space.

The Superior Carotid Triangle is bounded, behind, by the Stermo-mastoid; below, by the anterior belly of the Omo-hyoid; and above, by the posterior belly of the Digastic muscle. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and superficialis colli nerves. Its floor is formed by parts of the Thyro-hyoid, Hyo-glossus, and the inferior and middle Constrictor muscles of the pharynx. This space contains the upper part of the common carotid artery, which bifurcates opposite the upper border of the thyroid cartilage into the external and internal carotid. These vessels are occasionally somewhat concealed from view by the anterior margin of the Stermo-mastoid muscle, which overlaps them. The external and internal carotids lie side by side, the external being the more anterior of the two. The following branches of the external carotid are also met with in this space: the superior thyroid, running forward and downward; the lingual, directly forward; the facial, forward and upward; the occipital, backward; and the ascending pharyngeal directly upward on the inner side of the internal carotid. The veins met with are: the internal jugular, which lies on the outer side of the common and internal carotid arteries, and veins corresponding to the above-mentioned branches of the external carotid—viz. the superior thyroid, the lingual, facial, ascending pharyngeal, and sometimes the occipital,—all of which accompany their corresponding arteries and terminate in the internal jugular. The nerves in this space are the following: In front of the sheath of the common carotid is the descendens hypoglossi. The hypoglossal nerve crosses both carotids above, curving round the occipital artery at its origin. Within the sheath, between the artery and vein, and behind both, is the pneumogastric nerve; behind the sheath, the sympathetic. On the outer side of the vessels the spinal accessory nerve runs for a short distance before it pierces the Stermo-mastoid muscle; and on the inner side of the external carotid, just below the hyoid bone, may be seen the superior laryngeal nerve; and, still more inferiorly, the external laryngeal nerve. The upper part of the larynx and lower part of the pharynx are also found in the front part of this space.

The Submaxillary Triangle corresponds to the part of the neck immediately beneath the body of the jaw. It is bounded, above, by the lower border of the body of the jaw and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastic and Stylo-hyoid muscles; in front, by the anterior belly of the Digastic. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and ascending filaments of the superficial cervical nerves. Its floor is formed by the anterior belly of the Digastic, the Mylo-hyoid, and the Hyo-glossus muscles. This space contains, in front, the submaxillary gland, imbedded in the substance of which are the facial artery and vein and their glandular branches; beneath this gland, on the surface of the Mylo-hyoid muscle, are the submental artery and the mylo-hyoid artery and nerve. The back part of this space is separated from the front part by the stylo-maxillary ligament: it contains the external carotid artery, ascending deeply in the substance of the parotid gland; this vessel here lies in front of, and superficial to, the internal carotid, being crossed by the facial nerve, and gives off in its course the posterior auricular, temporal, and internal maxillary branches: more deeply are the internal carotid, the internal jugular vein, and the pneumogastric nerve, separated from the external carotid by the Styloglossus and Stylo-pharyngeus muscles and the glosso-pharyngeal nerve.1

1 The same remark will apply to this triangle as was made about the inferior carotid triangle. The structures enumerated as contained in the back part of the space lie, strictly speaking, beneath the muscles which form the posterior boundary of the triangle; but as it is very important to bear in mind their close relation to the parotid gland and its boundaries (on account of the frequency of surgical operations on this gland), all these parts are spoken of together.
Posterior Triangle of the Neck.

The posterior triangle is bounded, in front, by the Sterno-mastoid muscle; behind, by the anterior margin of the Trapezius; its base corresponds to the upper border of the clavicle; its apex, to the occiput. The space is crossed, about an inch above the clavicle, by the posterior belly of the Omo-hyoid, which divides it unequally into two, an upper or occipital and a lower or subclavian triangle.

The Occipital, the larger of the two posterior triangles, is bounded, in front, by the Sterno-mastoid; behind, by the Trapezius; below, by the Omo-hyoid. Its floor is formed from above downward by the Splenius capitis, Levator anguli scapulae, and the middle and posterior Scaleni muscles. It is covered by the integument, the Platysma below, the superficial and deep fasciae; the spinal accessory nerve is directed obliquely across the space from the Sterno-mastoid, which it pierces, to the under surface of the Trapezius; below, the descending branches of the cervical plexus and the transversalis colli artery and vein cross the space. A chain of lymphatic glands is also found running along the posterior border of the Sterno-mastoid, from the mastoid process to the root of the neck.

The Subclavian, the smaller of the two posterior triangles, is bounded, above, by the posterior belly of the Omo-hyoid; below, by the clavicle, its base, directed forward, being formed by the Sterno-mastoid. The size of the subclavian triangle varies according to the extent of attachment of the clavicular portion of the Sterno-mastoid and Trapezius muscles, and also according to the height at which the Omo-hyoid crosses the neck above the clavicle. Its height also varies much according to the position of the arm, being much diminished by raising the limb, on account of the ascent of the clavicle, and increased by drawing the arm downward, when that bone is depressed. This space is covered by the integument, superficial and deep fasciae, and crossed by the descending branches of the cervical plexus. Just above the level of the clavicle the third portion of the subclavian artery curves outward and downward from the outer margin of the Scalens anticus, across the first rib, to the axilla. Sometimes this vessel rises as high as an inch and a half above the clavicle, or to any point intermediate between this and its usual level. Occasionally, it passes in front of the Scalens anticus or pierces the fibres of that muscle. The subclavian vein lies behind the clavicle, and is usually not seen in this space; but it occasionally rises as high up as the artery, and has even been seen to pass with that vessel behind the Scalens anticus. The brachial plexus of nerves lies above the artery, and in close contact with it. Passing transversely across the clavicular margin of the space are the suprascapular vessels, and traversing its upper angle in the same direction, the transversalis colli artery and vein. The external jugular vein runs vertically downward behind the posterior border of the Sterno-mastoid, to terminate in the subclavian vein; it receives the transverse cervical and suprascapular veins, which occasionally form a plexus in front of the artery, and a small vein which crosses the clavicle from the cephalic. The small nerve to the Subclavious muscle also crosses this triangle about its middle. A lymphatic gland is also found in the space. Its floor is formed by the first rib with the first digitation of the Serratus magnus.

The Internal Carotid Artery.

The internal carotid artery supplies the anterior part of the brain, the eye, and its appendages, and sends branches to the forehead and nose. Its size in the adult is equal to that of the external carotid, though in the child it is larger than that vessel. It is remarkable for the number of curvatures that it presents in different parts of its course. In its cervical portion it occasionally presents one or two flexures near the base of the skull, whilst through the rest of its extent it describes a double curvature which resembles the italic letter s placed horizontally. These curvatures most probably diminish the velocity of the current of
blood, by increasing the extent of surface over which it moves and adding to the amount of impediment produced from friction.

In considering the course and relations of this vessel it may be conveniently divided into four portions: a cervical, petrous, cavernous, and cerebral.

**Cervical Portion.**—This portion of the internal carotid commences at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, and runs perpendicularly upward, in front of the transverse processes of the three upper cervical vertebrae, to the carotid canal in the petrous portion of the temporal bone. It is superficial at its commencement, being contained in the superior carotid triangle, and lying on the same level as the external carotid, but behind that artery overlapped by the Sterno-mastoid and covered by the deep fascia. Platysma, and integument: it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastric and Stylo-hyoid muscles, and the external carotid and occipital arteries. Higher up, it is separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, and pharyngeal branch of the pneumogastric. It is in relation, behind, with the Rectus capitis anticus major, the superior cervical ganglion of the sympathetic, and superior laryngeal nerve; externally, with the internal jugular vein and pneumogastric nerve; internally, with the pharynx, tonsil, the superior laryngeal nerve, and ascending pharyngeal artery.

**Petrosus Portion.**—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forward and inward, and again ascends as it leaves the canal to enter the cavity of the skull. In this canal the artery lies at first anterior to the tympanum, from which it is separated by a thin, bony lamella, which is cribiform in the young subject, and often absorbed in old age. It is separated from the bony wall of the carotid canal by a prolongation of dura mater, and is surrounded by filaments of the carotid plexus.

**Cavernous Portion.**—The internal carotid artery in this part of its course is situated between the layers of the dura mater forming the cavernous sinuses, but covered by the lining membrane of the sinuses. It at first ascends to the posterior clinoid process, then passes forward by the side of the body of the sphenoid bone, and again curves upward on the inner side of the anterior clinoid process, and perforates the dura mater forming the roof of the sinus. In this part of its course it is surrounded by filaments of the sympathetic nerve, and has in relation with it externally the sixth nerve.

**Cerebral Portion.**—Having perforated the dura mater on the inner side of the anterior clinoid process, the internal carotid enters the inner extremity of the fissure of Sylvius, where it gives off its terminal or cerebral branches. This portion of the artery has the optic nerve on its inner side, and the third nerve externally.

**Plan of the Relations of the Internal Carotid Artery in the Neck.**

**Externally.**
- Skin, superficial and deep fasciae.
- Platysma.
- Sterno-mastoid.
- External carotid and occipital arteries.
- Hypoglossal nerve.
- Parotid gland.
- Stylo-glossus and Stylo-pharyngeus muscles.
- Glosso-pharyngeal nerve.
- Pharyngeal branch of the pneumogastric.
- Internal jugular vein.
- Pneumogastric nerve.

**Internally.**
- Pharynx.
- Superior laryngeal nerve.
- Ascending pharyngeal artery.
- Tonsil.
Behind.
Rectus capitis anticus major.
Sympathetic.
Superior laryngeal nerve.

Peculiarities.—The length of the internal carotid varies according to the length of the neck, and also according to the point of bifurcation of the common carotid. Its origin some-

times takes place from the arch of the aorta; in such rare instances this vessel has been found to be placed nearer the middle line of the neck than the external carotid, as far upward as the larynx, when the latter vessel crossed the internal carotid. The course of the vessel, instead of being straight, may be very tortuous. A few instances are recorded in which this vessel was altogether absent; in one of these the common carotid passed up the neck, and gave off the usual branches of the external carotid, the cranial portion of the internal carotid being replaced by two branches of the internal maxillary, which entered the skull through the foramen rotundum and ovale and joined to form a single vessel.
Surgical Anatomy.—The cervical part of the internal carotid is very rarely wounded. Mr. Cripps, in an interesting paper in the *Medico-Chirurgical Transactions*, compares the rareness of a wound of the internal carotid with one of the external or its branches. It is, however, sometimes injured by a stab or gunshot wound in the neck, or even occasionally by a stab from within the mouth, as when a person receives a thrust from the end of a parasol or falls down with a tobacco-pipe in his mouth. The relation of the internal carotid with the tonsil should be especially remembered, as instances have occurred in which the artery has been wounded during the operation of securing the tonsil, and fatal hemorrhage has supervened. The indications for ligature are wounds, when the vessel should be exposed by a careful dissection and tied above and below the bleeding point; and aneurism, which if non-traumatic may be treated by ligature of the common carotid, but if traumatic in origin by exposing the sac and tying the vessel above and below. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Stero-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The superficial structures being divided and the Stero-mastoid defined and drawn outward, the cellular tissue must be carefully separated and the posterior belly of the Digastric and hypoglossal nerve sought for as guides to the vessel. When the artery is found the external carotid should be drawn inward and the Digastric muscles upward, and the aneurism needle passed from without inward.

The branches given off from the internal carotid are—

*From the Petrous portion.*
- Tympanic (internal or deep).

*From the Cavernous portion.*
- Arteriae Receptaculi.
- Anterior Meningeal.
- Ophthalmic.
- Anterior Cerebral.
- Middle Cerebral.
- Posterior Communicating.
- Anterior Choroid.

The cervical portion of the internal carotid gives off no branches.

The tympanic is a small branch which enters the cavity of the tympanum through a minute foramen in the carotid canal, and anastomoses with the tympanic branch of the internal maxillary, and with the stylo-mastoid artery.

The arteriae receptaculi are numerous small vessels, derived from the internal carotid in the cavernous sinus; they supply the pituitary body, the Gasserian ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of these branches Anastomose with branches of the middle meningeal.

The anterior meningeal is a small branch which passes over the lesser wing of the sphenoid to supply the dura mater of the anterior fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

The Ophthalmic Artery arises from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the inner side of the anterior clinoid process, and enters the orbit through the optic foramen, below and on the outer side of the optic nerve. It then passes over the nerve to the inner wall of the orbit, and thence horizontally forward, beneath the lower border of the Superior oblique muscle, to a point behind the internal angular process of the frontal bone, where it divides into two terminal branches, the *fron tal* and *nasal*.

Branches.—The branches of this vessel may be divided into an *orbital group*, which are distributed to the orbit and surrounding parts, and an *ocular group*, which supply the muscles and globe of the eye:

**Orbital Group.**
- Lachrymal.
- Supra-orbital.
- Posterior Ethmoidal.
- Anterior Ethmoidal.
- Palpebral.
- Frontal.
- Nasal.

**Ocular Group.**
- Muscular.
- Anterior Ciliary.
- Short Ciliary.
- Long Ciliary.
- Arteria Centralis Retinæ.

The lachrymal is the first and one of the largest branches derived from the ophthalmic, arising close to the optic foramen: not unfrequently it is given off...
from the artery before it enters the orbit. It accompanies the lachrymal nerve along the upper border of the External rectus muscle, and is distributed to the lachrymal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctivæ, anastomosing with the palpebral arteries. The lachrymal artery gives off one or two malar branches, one of which passes through a foramen in the malar bone, to reach the temporal fossa, and anastomoses with the deep temporal arteries; the other appears on the cheek and anastomoses with the transverse facial. A branch is also sent backward through the sphenoidal fissure to the dura mater, which anastomoses with a branch of the middle meningeal artery.

**Peculiarities.**—The lachrymal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

The *supra-orbital artery* arises from the ophthalmic as that vessel is crossing over the optic nerve. Ascending so as to arise above all the muscles of the orbit, it passes forward, with the supra-orbital nerve, between the periosteum and Levator palpebrae; and, passing through the supra-orbital foramen, divides into a superficial and deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the anterior branch of the temporal, and the artery of the opposite side. This artery in the orbit supplies the Superior rectus and the Levator palpebrae, and sends a branch inward, across the pulley of the Superior oblique muscle, to supply the parts at the inner canthus. At the supra-orbital foramen it frequently transmits a branch to the diploë.

The *ethmoidal branches* are two in number—posterior and anterior. The former, which is the smaller, passes through the posterior ethmoidal foramen, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater, and nasal branches which descend into the nose through apertures in the cribiform plate, anasto-

---

**FIG. 353.**—The ophthalmic artery and its branches, the roof of the orbit having been removed.
moming with branches of the sphenopalatine. The anterior ethmoidal artery accompanies the nasal nerve through the anterior ethmoidal foramen, supplies the anterior ethmoidal cells and frontal sinuses, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater, and nasal branches, which descend into the nose, through apertures in the cribiform plate.

The palpebral arteries, two in number, superior and inferior, arise from the ophthalmic, opposite the pulley of the Superior oblique muscle; they leave the orbit to encircle the eyelids near their free margin, forming a superior and an inferior arch, which lie between the Orbicularis muscle and tarsal plates; the superior palpebral inosculating at the outer angle of the orbit with the orbital branch of the temporal artery, and with a branch from the lachrymal artery—the inferior palpebral inosculating, at the outer angle of the orbit with a branch from the lachrymal and transverse facial arteries, and at the inner side of the lid with a branch from the angular artery. From this anastomosis a branch passes to the nasal duct, ramifying in its mucous membrane, as far as the inferior meatus.

The frontal artery, one of the terminal branches of the ophthalmic, passes from the orbit at its inner angle, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supraorbital artery and with the artery of the opposite side.

The nasal artery, the other terminal branch of the ophthalmic, emerges from the orbit above the tendo oculi, and, after giving a branch to the upper part of the lachrymal sac, divides into two branches, one of which anastomoses with the angular artery; the other, the dorsalis nasi, runs along the dorsum of the nose, supplies its entire surface, and anastomoses with the artery of the opposite side.

The ciliary arteries are divisible into three groups, the short, the long, and anterior. The short ciliary arteries, from six to twelve in number, arise from the ophthalmic or some of its branches; they surround the optic nerve as they pass forward to the posterior part of the eyeball, pierce the sclerotic coat around the entrance of the nerve, and supply the choroid coat and ciliary processes. The long ciliary arteries, two in number, also pierce the posterior part of the sclerotic, and run forward, along each side of the eyeball, between the sclerotic and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle around the circumference of the iris, from which numerous radiating branches pass forward, in its substance, to its free margin, where they form a second arterial circle around its pupillary margin. The anterior ciliary arteries are derived from the muscular branches; they pierce the sclerotic a short distance from the cornea, and terminate in the great arterial circle of the iris.

The arteria centralis retinae is one of the smallest branches of the ophthalmic artery. It arises from the ophthalmic as that vessel is about to cross over the optic nerve; it pierces the optic nerve obliquely, and runs forward in the centre of its substance, and enters the globe of the eye through the porus opticus. Its mode of distribution will be described in the account of the anatomy of the eye.

The muscular branches, two in number, superior and inferior, supply the muscles of the eyeball. The superior, the smaller, often wanting, supplies the Levator palpebrae, Superior rectus, and Superior oblique. The inferior, more constant in its existence, passes forward between the optic nerve and Inferior rectus, and is distributed to the External, Internal, and Inferior recti, and Inferior oblique. This vessel gives off most of the anterior ciliary arteries.

The cerebral branches of the internal carotid are—the anterior cerebral, the middle cerebral, the posterior communicating, and the anterior choroid.

The anterior cerebral arises from the internal carotid at the inner extremity of the fissure of Sylvius. It passes forward in the great longitudinal fissure between the two anterior lobes of the brain, being connected, soon after its origin, with the vessel of the opposite side by a short anastomosing trunk, about two lines in length, the anterior communicating. The two anterior cerebral arteries, lying side by side, curve round the anterior border of the corpus callosum, and run along its
BRANCHES OF THE INTERNAL CAROTID.

upper surface to its posterior part, where they terminate by anastomosing with the posterior cerebral arteries. In their course they give off the following branches:

- Antero-median ganglionic.
- Middle and Internal Frontal.
- Anterior and Internal Frontal.
- Posterior and Internal Frontal.

Fig. 354.—The arteries of the base of the brain. The right half of the cerebellum and pons have been removed.

N.B.—It will be noticed that in the illustration the two anterior cerebral arteries have been drawn at a considerable distance from each other: this makes the anterior communicating artery appear very much longer than it really is.

The antero-median ganglionic is a group of small arteries which arise at the
commencement of the anterior cerebral artery; they pierce the anterior perforated space and lamina cinerea, and supply the head of the caudate nucleus.

The anterior and internal frontal branches supply the two inferior frontal convolutions. The middle and internal frontal branches supply the corpus callosum, the convolution of the corpus callosum, the inner surface of the first frontal convolution, and the upper part of the ascending frontal convolution. The posterior and internal frontal branches supply the lobus quadratus.

The anterior communicating artery is a short branch, about two lines in length, but of moderate size, connecting together the two anterior cerebral arteries across the longitudinal fissure. Sometimes this vessel is wanting, the two arteries joining together to form a single trunk, which afterward divides. Or the vessel may be wholly or partially divided into two; frequently it is longer and smaller than usual. It gives off some of the antero-median ganglionic group of vessels, which are, however, principally derived from the anterior cerebral.

The middle cerebral artery (Fig. 356), the largest branch of the internal carotid, passes obliquely outward along the fissure of Sylvius, and opposite the island of Reil divides into its terminal branches. The branches of the middle cerebral artery are—

Antero-lateral Ganglionic. Ascending Frontal.
External and Inferior Frontal. Ascending Parietal.
Parieto-sphenoidal.

The antero-lateral ganglionic branches are a group of small arteries which arise at the commencement of the middle cerebral artery; they pierce the anterior perforated space and supply the greater part of the caudate nucleus, the lenticular nucleus, the internal capsule, and a part of the optic thalamus. One artery of this group, distributed to the lenticular nucleus, is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot the "artery of cerebral hemorrhage." The external and inferior frontal supplies the third or inferior frontal convolution (Broca's convolution). The ascending frontal supplies the ascending frontal convolution. The ascending parietal supplies the ascending parietal con-
volution. The parieto-sphenoidal supplies the superior temporo-sphenoidal convolution and the angular gyrus.

The posterior communicating artery arises from the back part of the internal carotid, runs directly backward, and anastomoses with the posterior cerebral, a branch of the basilar. This artery varies considerably in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other side. From the posterior half of this vessel are given off a number of small branches, the postero-median ganglionic branches, which, with similar vessels from the posterior cerebral, pierce the posterior perforated space and supply the internal surfaces of the optic thalami and the walls of the third ventricle.

The anterior choroid is a small but constant branch which arises from the back part of the internal carotid, near the posterior communicating artery. Passing backward and outward, it enters the descending horn of the lateral ventricle beneath the edge of the middle lobe of the brain. It is distributed to the hippocampus major, corpus fimbriatum, velum interpositum, and choroid plexus.

The Blood-vessels of the Brain.

Recent investigations have tended to show that the mode of distribution of the vessels of the brain has an important bearing upon a considerable number of the anatomical lesions of which this part of the nervous system may be the seat; it therefore becomes important to consider a little more in detail the way in which the cerebral vessels are distributed.

The cerebral arteries are derived from the internal carotid and the vertebral, which at the base of the brain form a remarkable anastomosis known as the circle of Willis. It is formed in front by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind by the two posterior cerebrials, branches of the basilar which are connected on each side with the internal carotid by the posterior communicating (Fig. 354, p. 573). The parts of the brain included within this arterial circle are the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

From the circle of Willis arise the three trunks which together supply each cerebral hemisphere. From its anterior part proceed the two anterior cerebrials, from its antero-lateral part the middle cerebral, and from its posterior part the
posterior cerebrials. Each of these principal arteries gives origin to two very
different systems of secondary vessels. One of these systems has been named the
central ganglionic system, and the vessels belonging to it supply the central ganglia
of the brain; the other has been named the cortical arterial system, and its vessels
ramify in the pia mater and supply the cortex and subjacent medullary matter.
These two systems, though they have a common origin, do not communicate at any
point of their peripheral distribution, and are entirely independent of each other.
Though some of the arteries of the cortical system approach, at their terminations,
the regions supplied by the central ganglionic system, no communication between
the two sets of vessels takes place, and there is between the parts supplied by
the two systems a borderland of diminished nutritive activity, where, it is said,
softening is especially liable to occur in the brains of old people.
The Central Ganglionic System.—All the vessels belonging to this system are
given off from the circle of Willis or from the vessels immediately after their origin

![Diagram of the arterial circulation at the base of the brain. (After Charcot.)](image)

and left postero-lateral group. The dotted line shows the limit of the ganglionic circle.

from it, so that if a circle is drawn at a distance of about an inch from the circle
of Willis, it will include the origin of all the arteries belonging to this system (Fig.
357). The vessels of this system form six principal groups: (I.) the antero-median
group, derived from the anterior cerebrials and anterior communicating; (II.) the
postero-median group, from the posterior cerebrials and posterior communicating;
(III.) the right and left antero-lateral group, from the middle cerebrials; and (IV.)
the right and left postero-lateral group, from the posterior cerebrials, after they have
wound round the crura cerebri. The vessels belonging to this system are larger
than those of the cortical system, and are what Cohnheim has termed "terminal"
arteries; that is to say, vessels which from their origin to their termination neither
supply nor receive any anastomotic branch, so that by one of the small vessels
only a limited area of the central ganglia can be injected; and the injection cannot
be driven beyond the area of the part supplied by the particular vessel which is the
subject of the experiment.
The Cortical Arterial System.—The vessels forming this system are the terminal
branches of the anterior, middle, and posterior cerebral arteries, described above.
These vessels divide and ramify in the substance of the pia mater, and give off nutrient arteries which penetrate the cortex perpendicularly. These nutrient vessels are divisible into two classes—the long and short. The long—or, as they are sometimes called, the medullary—arteries pass through the gray matter to penetrate the centrum ovale to the depth of about an inch and a half, without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The short vessels are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the gray matter, the outer and inner zones being sparingly supplied with blood (Fig. 358). The vessels of the cortical arterial system are not so strictly "terminal" as those of the central ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though it may be possible, is frequently very difficult, and is only effected through vessels of small calibre. As a result of this, obstruction of one of the main branches or its divisions may have the effect of producing softening in a very limited area of the cortex.  

**ARTERIES OF THE UPPER EXTREMITY.**

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow, but different portions of it have received different names according to the region through which it passes. That part of the vessel which extends from its origin to the lower border of the first rib is termed the subclavian; beyond this point to the lower border of the axilla it is termed the axillary; and from the lower margin of the axillary space to the bend of the elbow it is termed brachial; here the single trunk terminates by dividing into two branches, the radial and ulnar—an arrangement precisely similar to what occurs in the lower limb.  

1 The student who desires further information on this subject is referred to Charcot's *Localization of Cerebral and Spinal Diseases*, p. 42 et seq., whence the facts above given have been principally derived.
THE SUBCLAVIAN ARTERIES (Fig. 359).

The subclavian artery on the right side arises from the innominate artery opposite the right sterno-clavicular articulation; on the left side it arises from the arch of the aorta. It follows, therefore, that these two vessels must, in the first part of their course, differ in their length, their direction, and their relation with neighboring parts.

In order to facilitate the description of these vessels, more especially from a surgical point of view, each subclavian artery has been divided into three parts. The first portion, on the right side, passes upward and outward from the origin of the vessel to the inner border of the Scalenus anticus. On the left side it ascends nearly vertically, to gain the inner border of that muscle. The second part passes outward, behind the Scalenus anticus; and the third part passes from the outer margin of that muscle, beneath the clavicle, to the lower border of the first rib, where it becomes the axillary artery. The first portion of these two vessels differs so much in its course and in its relation with neighboring parts that it will be described separately. The second and third parts are alike on the two sides.
The right subclavian artery arises from the arteria innominata, opposite the right sterno-clavicular articulation, and passes upward and outward to the inner margin of the Scalenus anticus muscle. In this part of its course it ascends a little above the clavicle, the extent to which it does so varying in different cases. It is covered, in front, by the integument, superficial fascia, Platysma, deep fascia, the clavicular origin of the Sterno-mastoid, the Sterno-hyoid, and Sterno-thyroid muscles, and another layer of the deep fascia. It is crossed by the internal jugular and vertebral veins and by the pneumogastric, the cardiac branches of the sympathetic, and the phrenic nerve. Beneath, the artery is invested by the pleura, and behind, it is separated by a cellular interval from the Longus colli, the neck of the first rib, and the cord of the sympathetic nerve; the recurrent laryngeal nerve winds round the lower and back part of the vessel. The subclavian vein lies below the subclavian artery, immediately behind the clavicle.

**Plan of Relations of First Portion of the Right Subclavian Artery.**

**In front.**

**Beneath.**

- Pleura.

**Behind.**

- Recurrent laryngeal nerve.
- Sympathetic.
- Longus colli.
- Neck of first rib.

**First Part of the Left Subclavian Artery (Fig. 344).**

The left subclavian artery arises from the end of the arch of the aorta, opposite the fourth dorsal vertebra, and ascends nearly vertically to the inner margin of the Scalenus anticus muscle. This part of the vessel is, therefore, longer than the right, situated more deeply in the cavity of the chest, and directed nearly vertically upward, instead of arching outward like the vessel of the opposite side.

It is in relation, in front, with the pleura, the left lung, the pneumogastric, cardiac, and phrenic nerves, which lie parallel with it; the left carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein; and is covered by the Sterno-thyroid, Sterno-hyoid, and Sterno-mastoid muscles; it has the left carotid in front of, but not in contact with, it; behind, it is in relation with the oesophagus, thoracic duct, inferior cervical ganglion of the sympathetic, Longus colli, and vertebral column. To its inner side are the oesophagus, trachea, and thoracic duct; to its outer side, the pleura.

- Sterno-thyroid, Sterno-hyoid, and Sterno-mastoid muscles.
SECOND AND THIRD PARTS OF THE SUBCLAVIAN ARTERY (Fig. 347).

The Second Portion of the Subclavian Artery lies behind the Scalenus anticus muscle; it is very short, and forms the highest part of the arch described by that vessel.

Relations.—It is covered, in front, by the skin, superficial fascia, Platysma, deep cervical fascia, Sterno-mastoid, and by the phrenic nerve, which is separated from the artery by the Scalenus anticus muscle. Behind, it is in relation with the pleura and the middle Scalenus; above, with the brachial plexus of nerves; below, with the pleura. The subclavian vein lies below and in front of the artery, separated from it by the Scalenus anticus.

Pleura and Middle Scalenus.

The Third Portion of the Subclavian Artery passes downward and outward from the outer margin of the Scalenus anticus to the lower border of the first rib, where it becomes the axillary artery. This portion of the vessel is the most superficial, and is contained in a triangular space, the base of which is formed in front by the Sterno-mastoid, and the two sides by the Omo-hyoid above and the clavicle below.

Behind.
Scalenus medius.
Relations.—It is covered, in front, by the skin, the superficial fascia, the Platysma, deep cervical fascia; by the clavicle, the Subclavius muscle and the suprascapular artery and vein, and the transverse cervical vein; the clavicular descending branches of the cervical plexus and the nerve to the Subclavius muscle pass vertically downward in front of the artery. The external jugular vein crosses it at its inner side, and receives the suprascapular and transverse cervical veins, which occasionally form a plexus in front of it. The subclavian vein is below the artery, lying close behind the clavicle. Behind, it lies on the middle Scalenum muscle; above it, and to its outer side, is the brachial plexus and Omo-hyoid muscle; below, it rests on the upper surface of the first rib.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The origin of the right subclavian from the innominate takes place, in some cases, above the sterno-clavicular articulation, and occasionally, but less frequently, in the cavity of the thorax, below that joint. Or the artery may arise as a separate trunk from the arch of the aorta. In such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority of cases it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains some importance by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, at its upper or back part, and passes obliquely toward the right side, usually behind the aœsophagus and right carotid, sometimes between the aœsophagus and trachea to the upper border of the first rib, whence it follows its ordinary course. In very rare instances this vessel arises from the thoracic aorta, as low down as the fourth dorsal vertebra. Occasionally it perforates the anterior Scalenum; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Scalenum. The artery sometimes ascends as high as an inch and a half above the clavicle or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left carotid.

Surface Marking.—The course of the subclavian artery in the neck may be mapped out by describing a curve, with its convexity upward at the base of the posterior triangle. The inner end of this curve corresponds to the sterno-clavicular joint, the outer end to the centre of the lower border of the clavicle. The curve is to be drawn with such an amount of convexity that its mid-point reaches half an inch above the upper border of the clavicle. The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. It should be borne in mind that the posterior border of the Sterno-mastoid muscle corresponds to the outer border of the Scalenum anticus, so that the third portion of the artery, that part most accessible for operation, lies immediately external to the posterior border of the Sterno-mastoid.

Surgical Anatomy.—The relations of the subclavian arteries of the two sides having been examined, the student should direct his attention to a consideration of the best position in which compression of the vessel may be effected, or in what situation a ligature may be best applied in cases of aneurism or wound.

Compression of the subclavian artery is required in cases of operations about the shoulder, in the axilla, or at the upper part of the arm; and the student will observe that there is only one situation in which it can be effectually applied—viz. where the artery passes across the outer surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon, grasping the side of the neck, should press with his thumb in the angle formed by the posterior border of the Sterno-mastoid with the upper border of the clavicle, downward, backward, and inward against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backward, so as to compress the artery against the middle Scalenum and transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligature of the subclavian artery may be required in cases of wounds or of aneurism in the axilla, or in cases of aneurism on the cardiac side of the point of ligature; and the third part of the artery is that which is most favorable for an operation, on account of its being comparatively superficial and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurismal tumor in the axilla the artery is placed at a great depth from the surface, which materially increases the difficulty of the operation. Under these circumstances it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases its arch is about half an inch above the clavicle, occasionally as high as an inch and a half, and sometimes so low as to be on a level with its upper border. If the clavicle is displaced, these variations will necessarily make the operation more or less difficult according as the vessel is more or less accessible.

The chief points in the operation of tying the third portion of the subclavian artery are as follows: The patient being placed on a table in the horizontal position, with the head drawn
over to the opposite side and the shoulder depressed as much as possible, the integument should be drawn downward upon the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sterno-mastoid, to which may be added a short vertical incision meeting the preceding in its centre. The object in drawing the skin downward is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downward with the skin. The cervical fascia should be divided upon a director, and if the interval between the Trapezius and Sterno-mastoid muscles be insufficient for the performance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen toward the inner side of the wound: this and the suprascapular and transverse cervical veins, which terminate in it, should be held aside. If the external jugular vein is at all in the way and exposed to injury, it should be tied in two places and divided. The suprascapular artery should be avoided, and the Omo-hyoid muscle held aside if necessary. In the space beneath this muscle careful search must be made for the vessel; a deep layer of fascia and some connective tissue having been divided carefully, the outer margin of the Scalenus anticus muscle must be felt for; and, the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The aneurism needle may then be passed around the vessel from above downward and inward, so as to avoid including any of the branches of the brachial plexus. If the clavicle is so raised by the tumor that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the Scalenus anticus muscle; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery and the alteration in position of the surrounding parts.

The second part of the subclavian artery, from being that portion which rises highest in the neck, has been considered favorable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the Scalenus anticus muscle, upon which lies the phrenic nerve, and at the inner side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising internal to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurism encroaches on the neck, it may be necessary to divide the outer half or two-thirds of the Scalenus anticus muscle, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as ligature of the third portion, until the Scalenus anticus is exposed, when it is to be divided on a director (never to a greater extent than its outer two-thirds), and it immediately retracts. The operation is therefore merely an extension of ligature of the third portion of the vessel.

In those cases of aneurism of the axillary or subclavian artery which encroach upon the outer portion of the Scalenus muscle to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side this operation is almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is next to impossible to overcome. On the right side the operation is practicable, and has been performed, though never with success. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner: The patient being placed on the table in the horizontal position with the neck extended, an incision should be made along the upper border of the inner part of the clavicle, and a second along the inner border of the Sterno-mastoid, meeting the former at an angle. The sternal attachment of the Sterno-mastoid may now be divided on a director and turned outward; a few small arteries and veins, and occasionally the anterior jugular, must be avoided, or, if necessary, ligatured in two places and divided, and the Sterno-hyoid and Sterno-thyroid muscles divided in the same manner as the preceding muscle. After tearing through the deep fascia with the finger-nail, the internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside and the artery secured by passing the needle from below upward, by which the pleura is more effectually avoided. The exact position of the vagus nerve, the recurrent laryngeal, the phrenic and sympathetic nerves should be remembered, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a conglomur between the ligature and the origin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course when it arises from the left side of the aortic arch, and passes in such cases behind the oesophagus or between it and the trachea.

**Collateral Circulation.**—After ligature of the third part of the subclavian artery the collateral circulation is mainly established by three sets of vessels, thus described in a dissection:

1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, anastomosing with the median branch from the subscapular from the axillary.
2. An internal set produced by the connection of the internal mammary on the one hand,

---

1 The operation was, however, performed in New York by Dr. J. K. Rodgers, and the case is related in *A System of Surgery*, edited by T. Holmes, 2d ed. vol. iii. pp. 620, etc.
with the superior and long thoracic arteries, and the branches from the subscapular on the other.

3. A middle or axillary set, which consisted of a number of small vessels derived from branches of the subclavian, above, and, passing through the axilla, terminated either in the main trunk or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of newly-formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

The chief agent in the restoration of the axillary artery below the tumor was the subscapular artery, which communicated most freely with the internal mammary, suprascapular, and posterior scapular branches of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size.

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by—1, the anastomosis between the superior and inferior thyroid; 2, the anastomosis of the two vertebrals; 3, the anastomosis of the internal mammary with the deep epigastric and the aortic intercostals; 4, the superior intercostal anastomosing with the aortic intercostals; 5, the profunda cervicis anastomosing with the princeps cervicis; 6, the scapular branches of the thyroid axis anastomosing with the branches of the axillary; and 7, the thoracic branches of the axillary anastomosing with the aortic intercostals.

Branches of the Subclavian Artery.

These are four in number. On the left side all four branches, the vertebral, the internal mammary, the thyroid axis, and the superior intercostal, generally arise from the first portion of the vessel; but on the right side the superior intercostal usually arises from the second portion of the vessel. On both sides of the body the first three branches arise close together at the inner margin of the Scalenus anticus, in the majority of cases a free interval of half an inch to an inch existing between the commencement of the artery and the origin of the nearest branch; in a smaller number of cases an interval of more than an inch exists, never exceeding an inch and three-quarters. In a very few instances the interval had been found to be less than half an inch.

The Vertebral Artery (Fig. 352) is generally the first and largest branch of the subclavian; it arises from the upper and back part of the first portion of the vessel, and, passing upward, enters the foramen in the transverse process of the sixth cervical vertebra, and ascends through the foramina in the transverse processes of all the vertebrae above this. Above the upper border of the axis it inclines outward and upward to the foramen in the transverse process of the atlas, through which it passes; it then winds backward behind its articular process, runs in a deep groove on the upper surface of the posterior arch of this bone, and, passing beneath the posterior occipito-atlantal ligament, pierces the dura mater and enters the skull through the foramen magnum. It then passes forward and upward to the front of the medulla oblongata, and unites with the vessel of the opposite side at the lower border of the pons Varolii to form the basilar artery.

Relations.—At its origin it is situated behind the internal jugular vein and inferior thyroid artery; and near the spine it lies between the Longus colli and Scalenus anticus muscles, having the thoracic duct in front of it on the left side. Within the foramina formed by the transverse processes of the vertebra it is accompanied by a plexus of nerves from the inferior cervical ganglion of the sympathetic, and is surrounded by a dense plexus of veins which unite to form the

---

1 Guy's Hospital Reports, vol. i. 1836: case of axillary aneurism, in which Mr. Astor Key had tied the sub clavian artery on the outer edge of the Scalenus muscle twelve years previously.

2 The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Dr. Smyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.
vertebral vein at the lower part of the neck. It is situated in front of the cervical nerves as they issue from the intervertebral foramina. Whilst winding round the articular process of the atlas it is contained in a triangular space (suboccipital triangle) formed by the Rectus capitis posticus major, the Superior and the Inferior oblique muscles; and at this point is covered by the Complexus muscle. Within the skull, as it winds round the medulla oblongata, it is placed between the hypoglossal nerve and the anterior root of the suboccipital nerve, beneath the first digitation of the ligamentum denticulatum, and finally lies between the dura mater covering the basilar process of the occipital bone and the anterior surface of the medulla oblongata.

Branches.—These may be divided into two sets—those given off in the neck and those within the cranium.

The lateral spinal branches enter the spinal canal through the intervertebral foramina and divide into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the artery above and below, so that two lateral anastomotic chains are formed on the posterior surface of the bodies of the vertebrae near the attachment of the pedicles. From these anastomotic chains branches are given off to supply the periosteum and the bodies of the vertebrae, and to communicate with similar branches from the opposite side; from these latter small branches are given off which join similar branches above and below, so that a central anastomotic chain is formed on the posterior surface of the bodies of the vertebrae.

Muscular branches are given off to the deep muscles of the neck, where the vertebral artery curves round the articular process of the atlas. They anastomose with the occipital and with the ascending and deep cervical arteries.

The posterior meningeal are one or two small branches given off from the vertebral opposite the foramen magnum. They ramify between the bone and dura mater in the cerebellar fossae, and supply the falx cerebelli.

The anterior spinal is a small branch, though larger than the posterior spinal, which arises near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow of the opposite side at about the level of the foramen magnum. The single trunk, thus formed, descends on the front of the spinal cord, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina; these branches are derived from the vertebral and ascending cervical of the inferior thyroid in the neck; from the intercostal in the dorsal region; and from the lumbar, ilio-lumbar, and lateral sacral arteries in the lower part of the spine. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord. This vessel is placed in the pia mater along the anterior median fissure: it supplies that membrane and the substance of the cord, and sends off branches at its lower part to be distributed to the cauda equina, and ends on the central fibrous prolongation of the cord.

The posterior spinal arises from the vertebral at the side of the medulla oblongata: passing backward to the posterior aspect of the spinal cord, it descends on each side, lying behind the posterior roots of the spinal nerves, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina, and by which it is continued to the lower part of the
cord and to the cauda equina. Branches from these vessels form a free anastomosis round the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessel of the opposite side. At its commencement it gives off an ascending branch, which terminates on the side of the fourth ventricle.

The posterior inferior cerebellar artery (Fig. 354), the largest branch of the vertebral, winds backward round the upper part of the medulla oblongata, passing between the origin of the pneumogastric and spinal accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two branches—an internal one, which is continued backward to the notch between the two hemispheres of the cerebellum; and an external one, which supplies the under surface of the cerebellum as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

Surgical Anatomy.—The vertebral artery has been tied in several instances: 1, for wounds or traumatic aneurism; 2, after ligature of the innominate, either at the same time to prevent haemorrhage, or later on to arrest bleeding where it has occurred at the seat of ligature; and 3, in epilepsy. In these latter cases the treatment has been recommended by Dr. Alexander of Liverpool, in the hope that by diminishing the supply of blood to the posterior part of the brain and the spinal cord a diminution or cessation of the epileptic fits would result. The operation of ligature of the vertebral is performed by making an incision along the posterior border of the Sterno-mastoid muscle, just above the clavicle. The muscle is pulled to the inner side, and the anterior tubercle of the transverse process of the sixth cervical vertebra sought for. A deep layer of fascia being now divided, the interval between the Scaenus anticus and the Longus colli just below their insertion into the tubercle is defined, and the artery and vein found in the interspace. The vein is to be drawn to the outer side, and the aneurism needle passed from without inward. Drs. Ramskill and Bright have pointed out that severe pain at the back of the head may be symptomatic of disease of the vertebral artery just before it enters the skull. This is explained by the close connection of the artery with the sub-occipital nerve in the groove on the posterior arch of the atlas. Disease of the same artery has been also said to affect speech, from pressure on the hypoglossal where it is in relation with the vessel, leading to paralysis of the muscles of the tongue.

The Basilar Artery, so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons Varolii, lying in its median groove, under cover of the arachnoid. It ends by dividing into two branches, the posterior cerebral arteries. Its branches are, on each side, the following:

Transverse.
Anterior Inferior Cerebellar.
Superior Cerebellar.
Posterior Cerebral.

The transverse branches supply the pons Varolii and adjacent parts of the brain, one branch, the internal auditory, accompanies the auditory nerve into the internal auditory meatus; and another, the anterior inferior cerebellar artery, passes across the crus cerebelli, to be distributed to the anterior border of the under surface of the cerebellum. The superior cerebellar arteries arise near the termination of the basilar. They wind round the crus cerebri close to the fourth nerve, and, arriving at the upper surface of the cerebellum, divide into branches which ramify in the pia mater and anastomose with the branches of the inferior cerebellar artery. Several branches are given to the pineal gland and also to the velum interpositum.

The posterior cerebral arteries, the two terminal branches of the basilar, are larger than the preceding, from which they are separated near their origin by the third nerves. Winding round the crus cerebri, they pass to the under surface of the occipital lobes of the cerebrum and divide into three main branches. Near their origin they receive the posterior communicating arteries from the internal carotid. The branches of the posterior cerebral artery are—

Postero-median Ganglionic.
Postero-lateral Ganglionic.
Posterior Choroid.
Three Terminal.
The postero-median ganglionic branches (Fig. 357) are a group of small arteries which arise at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated space and supply the internal surfaces of the optic thalami and the walls of the third ventricle. The posterior choroid enters the interior of the brain beneath the posterior border of the corpus callosum and supplies the velum interpositum and the choroid plexus. The postero-lateral ganglionic branches are a group of small arteries which arise from the posterior cerebral artery after it has turned round the crus cerebri; they supply a considerable portion of the optic thalamus. The terminal branches are distributed as follows: the first to the uncinate gyrus; the second to the temporo-sphenoidal lobe; and the third to the cuneus or the occipital lobule.

Circle of Willis.—The remarkable anastomosis which exists between the branches of the internal carotid and vertebral arteries at the base of the brain constitutes the circle of Willis. It is formed, in front, by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind, by the two posterior cerebri, branches of the basilar, which are connected on each side with the internal carotid by the posterior communicating arteries (Fig. 354). It is by this anastomosis that the cerebral circulation is equalized, and provision made for effectually carrying it on if one or more of the branches are obliterated. The parts of the brain included within this arterial circle are—the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

The Thyroid Axis (Fig. 347) is a short thick trunk which arises from the fore part of the first portion of the subclavian artery, close to the inner border of the Scalenus anticus muscle, and divides, almost immediately after its origin, into three branches—the inferior thyroid, supra-scapular, and transversalis colli.

The Inferior Thyroid Artery passes upward, in a serpentine course, behind the sheath of the common carotid vessel and sympathetic nerve (the middle cervical ganglion resting upon it), and in front of the vertebral artery, recurrent laryngeal nerve (sometimes behind the nerve), and Longus colli muscle, and is distributed to the posterior surface of the thyroid gland, anastomosing with the superior thyroid and with the corresponding artery of the opposite side. Its branches are—the

Muscular.

The inferior laryngeal branch ascends upon the trachea to the back part of the larynx, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the branch from the opposite side and with the laryngeal branch from the superior thyroid artery.

The tracheal branches are distributed upon the trachea, anastomosing below with the bronchial arteries.

The oesophageal branches are distributed to the oesophagus, and anastomose with the oesophageal branches of the aorta.

The ascending cervical is a small branch which arises from the inferior thyroid just where that vessel is passing behind the common carotid artery, and runs up on the anterior tuberces of the transverse processes of the cervical vertebrae in the interval between the Scalenus anticus and Rectus capitis anticus major. It gives branches to the muscles of the neck, which anastomose with branches of the vertebral, and sends one or two branches into the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebrae in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal artery.

The muscular branches supply the depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx.
Surgical Anatomy.—This artery is sometimes tied, in conjunction with the superior thyroid, in cases of bronchocele. An incision is made along the anterior border of the Sterno-mastoimd down to the clavicle. After the deep fascia has been divided, the Sterno-mastoid and carotid vessels are drawn outward and the carotid (Chassaignac's) tubercle sought for. The vessel will be found just below this tubercle, between the carotid sheath on the outer side of the trachea and oesophagus on the inner side. In passing the ligature great care must be exercised to avoid including the recurrent laryngeal nerve.

The Suprascapular Artery (transversalis humeri), smaller than the transversalis colli, passes obliquely from within outward, across the root of the neck. It at first lies on the lower part of the Scalenum anticus, being covered by the Sterno-mastoid; it then crosses the subclavian artery, and runs outward behind and parallel with the clavicle and Subclavius muscle, and beneath the posterior belly of the Omo-hyoid, to the superior border of the scapula, where it passes over the transverse ligament of the scapula to the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus muscle, to which it is mainly distributed, giving off a communicating branch which crosses the neck of the scapula, to reach the infraspinous fossa, where it anastomoses with the dorsal branch of the subscapular artery. Besides distributing branches to the Sterno-mastoid and neighboring muscles, it gives off a supra-acromial branch, which, piercing the Trapezius muscle, supplies the cutaneous surface of the acromion, anastomosing with the acromial thoracic artery. As the artery passes over the transverse ligament of the scapula a branch descends into the subscapular fossa, ramifies beneath that muscle, and anastomoses with the posterior and sub-scapular arteries. It also supplies the shoulder-joint and a nutrient branch to the clavicle.

The Transversalis Colli passes transversely outward, across the upper part of the subclavian triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the superficial cervical and the posterior scapular. In its passage across the neck it crosses in front of the Scaleni muscles and the brachial plexus, between the divisions of which it sometimes passes, and is covered by the Platysma, Sterno-mastoid, Omo-hyoid, and Trapezius muscles.

The superficial cervical ascends beneath the anterior margin of the Trapezius, distributing branches to it and to the neighboring muscles and glands in the neck, and anastomoses with the superficial branch of the arteria princeps cervicis.

The posterior scapular, the continuation of the transversalis colli, passes...
beneath the Levator anguli scapulae to the superior angles of the scapula. It now descends along the posterior border of that bone as far as the inferior angle, where it anastomoses with the subscapular branch of the axillary. In its course it is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The superficial cervical frequently arises as a separate branch from the thyroid axis: and the posterior scapular, from the third, more rarely from the second, part of the subclavian. This arrangement is almost as common as the one already given.

The Internal Mammary arises from the under surface of the first portion of the subclavian artery, opposite the thyroid axis. It descends behind the costal cartilage of the first rib to the inner surface of the anterior wall of the chest, resting against the costal cartilages about half an inch from the margin of the sternum; and at the interval between the sixth and seventh cartilages divides into two branches, the musculo-phrenic and superior epigastric.

Relations.—At its origin it is covered by the internal jugular and subclavian veins and crossed by the phrenic nerve. In the upper part of the thorax it lies against the costal cartilages and Internal intercostal muscles in front, and is covered by the pleura behind. At the lower part of the thorax the Triangularis sterni separates the artery from the pleura.

The branches of the internal mammary are—

</tr>
</tbody>
</table>

The comes nervi phrenici (superior phrenic), is a long slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm, to which it is distributed, anastomosing with the other phrenic arteries from the internal mammary and abdominal aorta.

The mediastinal branches are small vessels which are distributed to the areolar tissue and lymphatic glands in the anterior mediastinum and the remains of the thymus gland.

The pericardiac branches supply the upper part of the anterior surface of the pericardium, the lower part receiving branches from the musculo-phrenic artery.

The sternal branches are distributed to the Triangularis sterni and to the posterior surface of the sternum.

The mediastinal, pericardiac, and sternal branches, together with some twigs from the comes nervi phrenici, anastomose with branches from the intercostal and bronchial arteries, and form a minute plexus beneath the pleura, which has been named by Turner the subpleural mediastinal plexus.

The anterior intercostal arteries supply the five or six upper intercostal spaces. The branch corresponding to each space soon divides into two, or the two branches may come off separately from the parent trunk. The small vessels pass outward in the intercostal spaces, one lying near the lower margin of the rib above, and the other near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Internal and External intercostal muscles. They supply the Intercostal muscles, and, by branches which perforate the External intercostal muscle, the Pectoralis muscles and the mammary gland.

The perforating arteries correspond to the five or six upper intercostal spaces. They arise from the internal mammary, pass forward through the intercostal spaces, and, curving outward, supply the Pectoralis major and the integument. Those which correspond to the second, third, and fourth spaces are distributed to the mammary gland. In females, during lactation, these branches are of large size.

The musculo-phrenic artery is directed obliquely downward and outward,
behind the cartilages of the false ribs, perforating the Diaphragm at the eighth or ninth rib, and terminating, considerably reduced in size, opposite the last intercostal space. It gives off anterior intercostal arteries to each of the intercostal spaces across which it passes; these diminish in size as the spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculo-phrenic also gives branches to the lower part of the pericardium, and others which run backward to the Diaphragm and downward to the abdominal muscles.

The superior epigastric continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating it and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some vessels perforate the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch, which passes inward upon the side of the ensiform appendix, anastomoses in front of that cartilage with the artery of the opposite side.

Surgical Anatomy.—The course of the internal mammary artery may be defined by drawing a line across the six upper intercostal spaces half an inch from and parallel with the sternum. The position of the vessel must be remembered, as it is liable to be wounded in stabs of the chest-wall. It is most easily reached by a transverse incision in the second intercostal space.

The Superior Intercostal (Fig. 352) arises from the upper and back part of the subclavian artery, behind the Anterior scalenus on the right side, and to the inner side of the muscle on the left side. Passing backward, it gives off the deep cervical branch, and then descends behind the pleura in front of the necks of the first two ribs, and inosculates with the first aortic intercostal. In the first intercostal space it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the aortic intercostals. Each intercostal gives off a branch to the posterior spinal muscles, and a small one, spinal, which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The deep cervical branch (profunda cervicis) arises, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery. Passing backward, between the transverse process of the seventh cervical vertebra and the first rib, it runs up the back part of the neck, between the Complexus and Semispinalis colli muscles, as high as the axis, supplying these and adjacent muscles, and anastomosing with the deep branch of the arteria princeps cervicis of the occipital and with branches which pass outward from the vertebral.

SURGICAL ANATOMY OF THE AXILLA.

The Axilla is a pyramidal space, situated between the upper and lateral part of the chest and the inner side of the arm.

Boundaries.—Its apex, which is directed upward toward the root of the neck, corresponds to the interval between the first rib, the upper edge of the scapula, and the clavicle, through which the axillary vessels and nerves pass. The base, directed downward, is formed by the integument, and a thick layer of fascia extending between the lower border of the Pectoralis major in front, and the lower border of the Latissimus dorsi behind; it is broad internally at the chest, but narrow and pointed externally at the arm. The anterior boundary is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall of the axilla, the latter covering only its central part. The posterior boundary, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the inner side are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the outer side, where the anterior and posterior boundaries

1 See foot-note, p. 607.
converge, the space is narrow, and bounded by the humerus, the Coraco-brachialis and Biceps muscles.

**Contents.**—This space contains the axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue.

**Their Position.**—The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axillary space, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the fore part of the axillary space, in contact with the Pectoral muscles, are the thoracic branches of the axillary artery, and along the anterior margin of the axilla the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis muscle, are the subscapular vessels and nerves; winding around the lower border of this muscle is the dorsalis scapulae artery and veins; and toward the outer extremity of the muscle the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation—viz. the posterior thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercosto-humeral nerve or nerves, passing across the axilla to the inner side of the arm.

The cavity of the axilla is filled by a quantity of loose areolar tissue and a large number of small arteries and veins, all of which are, however, of inconsiderable

![Fig. 362.—The axillary artery and its branches.](image-url)
size, and numerous lymphatic glands: these are from ten to twelve in number, and situated chiefly on the thoracic side and lower and back part of this space.

Surgical Anatomy.—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease: it contains numerous lymphatic glands which may require removal when diseased; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or inflammatory exudation, and it may be the seat of rapidly-growing tumors. Moreover, it is covered at its base by thin skin, largely supplied with sebaceous and sweat glands, which is frequently the seat of small cutaneous abscesses and boils, and of eruptions due to irritation.

In suppuration in the axilla the arrangement of the fascia plays a very important part in the direction which the pus takes. As described on page 468, the costo-coracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and, reblending at its lower border, becomes incorporated with the fascia covering the Pectoralis major muscle at the anterior fold of the axilla. This is known as the clavi-pectoral fascia. Suppuration may take place either superficial to or beneath this layer of fascia: that is, either between the pectorals or below the pectoralis minor: in the former case, it would point either at the anterior border of the axillary fold or in the groove between the Deltoïd and the Pectoralis major: in the latter, the pus would have a tendency to surround the vessels and nerves and ascend into the neck, that being the direction in which there is least resistance. Its progress toward the skin is prevented by the axillary fascia: its progress backward, by the Serratus magnus; forward, by the clavi-pectoral fascia; inward, by the wall of the thorax; and outward, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum.

In opening an axillary abscess the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. It is well to use a director and dressing forceps after an incision has been made through the skin and fascia in the manner directed by the late Mr. Hilton.

The student should attentively consider the relation of the vessels and nerves in the several parts of the axilla, for it not unfrequently happens that the surgeon is called upon to extirpate diseased glands or to remove a tumor from this situation. In performing such an operation it will be necessary to proceed with much caution in the direction of the outer wall and apex of the space, as here the axillary vessels will be in danger of being wounded. Toward the posterior wall it will be necessary to avoid the subscapular, dorsalis scapulae, and posterior circumflex vessels. Along the anterior wall it will be necessary to avoid the thoracic branches. It is only along the inner or thoracic wall, and in the centre of the axillary cavity, that there are no vessels of any importance—a fortunate circumstance, for it is in this situation more especially that tumors requiring removal are usually situated.

THE AXILLARY ARTERY.

The Axillary Artery, the continuation of the subclavian, commences at the lower border of the first rib, and terminates at the lower border of the tendon of the Teres major muscle, where it takes the name of brachial. Its direction varies with the position of the limb: when the arm lies by the side of the chest, the vessel forms a gentle curve, the convexity being upward and outward; when it is directed at right angles with the trunk, the vessel is nearly straight; and when it is elevated still higher, the artery describes a curve the concavity of which is directed upward. At its commencement the artery is very deeply situated, but near its termination is superficial, being covered only by the skin and fascia. The description of the relations of this vessel is facilitated by its division into three portions, the first portion being that above the Pectoralis minor; the second portion, behind; and the third below, that muscle.

The first portion of the axillary artery is in relation, in front, with the clavicular portion of the Pectoralis major, the costo-coracoid membrane, the external anterior thoracic nerve, and the acromio-thoracic and cephalic veins; behind, with the first intercostal space, the corresponding Intercostal muscle, the second and third serrations of the Serratus magnus, and the posterior thoracic nerve; on its outer side, with the brachial plexus, from which it is separated by a little cellular interval; on its inner or thoracic side, with the axillary vein.

Relations of the First Portion of the Axillary Artery.

In front.

Pectoralis major.
Costo-coracoid membrane.
External anterior thoracic nerve.
Acromio-thoracic and Cephalic veins.
The second portion of the axillary artery lies behind the Pectoralis major. It is covered in front, by the Pectoralis major and minor muscles; behind, it is separated from the Subscapularis by a cellular interval; on the inner side is the axillary vein. The cords of the brachial plexus of nerves surround the artery, and separate it from direct contact with the vein and adjacent muscles.

The third portion of the axillary artery lies below the Pectoralis minor. It is in relation, in front, with the lower part of the Pectoralis major above, being covered only by the integument and fascia below, where it is crossed by the inner head of the median nerve; behind, with the lower part of the Subscapularis and the tendons of the Latissimus dorsi and Teres major; on its outer side, with the Coraco-brachialis; on its inner or thoracic side, with the axillary vein. The nerves of the brachial plexus bear the following relation to the artery in this part of its course: on the outer side is the median nerve, and the musculo-cutaneous for a short distance; on the inner side, the ulnar, the internal, and lesser internal cutaneous nerves; and behind, the musculo-spiral and circumflex, the latter extending only to the lower border of the Subscapularis muscle.

Peculiarities.—The axillary artery, in about one case out of every ten, gives off a large branch, which forms either one of the arteries of the forearm or a large muscular trunk. In the first set of cases this artery is most frequently the radial (1 in 33), sometimes the ulnar (1 in 72), and, very rarely, the interosseous (1 in 506). In the second set of cases the trunk has been found to give origin to the subscapular, circumflex, and profunda arteries of the arm. Sometimes only one of the circumflex, or one of the profunda arteries, arose from the trunk. In these cases the brachial plexus surrounded the trunk of the branches, and not the main vessel.

THE AXILLARY ARTERY.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coraco-brachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coraco-brachialis.

Surgical Anatomy.—The student, having carefully examined the relations of the axillary artery in its various parts, should now consider in what situation compression of this vessel may be most easily effected, and the best position for the application of a ligature to it when necessary.

Compression of the vessel may be required in the removal of tumors or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outward against the humerus the circulation may be effectually arrested.

The axillary artery is perhaps more frequently lacerated than any other artery in the body, with the exception of the popliteal, by violent movements of the upper extremity, especially in those cases where its coats are diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder-joint. This lesion is most likely to occur during the preliminary breaking down of adhesions, in consequence of the artery having contracted adhesions to the capsule of the joint. Aneurism of the axillary artery is of frequent occurrence, a large percentage of the cases being traumatic in their origin, due to the violence to which it is exposed in the varied, extensive, and often violent movement of the limb.

The application of a ligature to the axillary artery may be required in cases of aneurism of the upper part of the brachial or as a distal operation for aneurism of the subclavian; and there are only two situations in which it can be secured—viz, in the first and in the third part of its course for the axillary artery at its central part is so deeply seated, and, at the same time, so closely surrounded with large nervous trunks, that the application of a ligature to it in that situation would be almost impracticable.

In the third part of its course the operation is most simple, and may be performed in the following manner: The patient being placed on a bed and the arm separated from the side, with the hand supinated, an incision is made through the integument forming the floor of the axilla about two inches in length, a little nearer to the anterior than the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former having been displaced to the outer and the latter to the inner side of the arm, the elbow being at the same time bent, so as to relax the structures and facilitate their separation, the ligature may be passed round the artery from the ulnar to the radial side. This portion of the artery is occasionally crossed by a muscular slip derived from the Latissimus dorsi, which may mislead the surgeon during an operation. The occasional existence of this muscular fasciculus was spoken of in the description of the muscles. It may easily be recognized by the transverse direction of its fibres.

The first portion of the axillary artery may be tied in cases of aneurism encroaching so far upward that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few cases, and with success, its performance is attended with much difficulty and danger. The student will remark that in this situation it would be necessary to divide a thick muscle, and, after separating the costo-coracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to this part of the artery one of the most hazardous. In such circumstances it is indeed at the same time more advisable, operation to tie the subclavian artery in the third part of its course.

The vessel can be best secured by a curved incision with the convexity downward from a point half an inch external to the Sterno-clavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and this incision carried through the superficial structures, care being taken of the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now to be brought to the side, and the upper edge of the Pectoralis minor defined and drawn downward. The costo-coracoid membrane is to be carefully torn through with a director close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein from above.

In a case of wound of the vessel the general practice of cutting down upon, and tying it above and below the wounded point should be adopted in all cases.

Collateral Circulation after Ligature of the Axillary Artery.—If the artery be tied above the origin of the acromial thoracic, the collateral circulation will be carried on by the same branches as after the ligature of the subclavian; if at a lower point, between the acromial thoracic and subcapular arteries, the latter vessel, by its free anastomoses with the other scapular arteries, branches of the subclavian, will become the chief agent in carrying on the circulation, to which the long thoracic, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature be below the origin of the subcapular artery, it will most probably also be below the origins of the two circumflex arteries. The chief agents in restoring the circulation will then be
the subscapular and the two circumflex arteries anastomosing with the superior profunda from the brachial.

**Branches of the Axillary Artery.**

The branches of the axillary artery are—

*From first part*  
- Superior Thoracic.  
- Acromial Thoracic.  

*From second part*  
- Long Thoracic.  
- Alar Thoracic.

*From third part*  
- Subscapular.  
- Anterior Circumflex.  
- Posterior Circumflex.

The **superior thoracic** is a small artery which arises from the axillary separately or by a common trunk with the acromial thoracic. Running forward and inward along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the chest. It supplies these muscles and the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

The **acromial thoracic** is a short trunk which arises from the fore part of the axillary artery. Projecting forward to the upper border of the Pectoralis minor, it divides into three sets of branches—thoracic, acromial, and descending or humeral. The thoracic branches, two or three in number, are distributed to the Serratus magnus and Pectoral muscles, anastomosing with the intercostal branches of the internal mammary. The acromial branches are directed outward toward the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular and posterior circumflex arteries. The humeral branch passes in the space between the Pectoralis major and Deltoid in the same groove as the cephalic vein, and supplies both muscles. The artery also gives off a very small branch, the clavicular, which passes upward to the Subclavius muscle.

The **long thoracic (external mammary)** passes downward and inward along the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus magnus, the Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary glands and Subscapularis; it anastomoses with the internal mammary and intercostal arteries. An accessory external mammary branch is often found running to the chest behind the long thoracic.

The **alar thoracic** is a small branch which supplies the glands and arcular tissue of the axilla. Its place is frequently supplied by branches from some of the other thoracic arteries.

The **subscapular**, the largest branch of the axillary artery, arises opposite the lower border of the Subscapularis muscle, and passes downward and backward along its lower margin to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular. About an inch and a half from its origin it gives off a large branch, the dorsalis scapulae, and terminates by supplying branches to the muscles in the neighborhood.

The **dorsalis scapulae** is given off from the subscapular about an inch from its origin, and is generally larger than the continuation of the vessel. It curves round the axillary border of the scapula, leaving the axilla through the space between the Teres minor above, the Teres major below, and the long head of the Triceps externally (Fig. 361), and enters the infraspinous fossa, where it anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two sets of branches: one enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and, at the dorsal surface of the inferior angle of the bone, anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.
The circumflex arteries wind round the neck of the humerus. The posterior circumflex (Fig. 361), the larger of the two, arises from the back part of the axillary opposite the lower border of the Subscapularis muscle, and, passing backward with the circumflex veins and nerve through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus, winds round the neck of that bone and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex and acromial thoracic arteries, and with the superior profunda branch of the brachial artery. The anterior circumflex (Figs. 361, 362), considerably smaller than the preceding, arises just below that vessel from the outer side of the axillary artery. It passes horizontally outward beneath the Coraco-brachialis and short head of the Biceps, lying upon the fore part of the neck of the humerus, and, on reaching the bicipital groove, gives off an ascending branch which passes upward along the groove to supply the head of the bone and the shoulder-joint. The trunk of the vessel is then continued outward beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery. The axillary cutaneous branch, long and slender, is often found ramifying in the superficial fascia of the floor of the axilla.

THE BRACHIAL ARTERY (Fig. 363).

The Brachial Artery commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the radial and ulnar arteries.

PLAN OF THE RELATIONS OF THE BRACHIAL ARTERY.

**In front.**
- Integument and fascia.
- Bicipital fascia, median basilic vein.
- Median nerve.

**Behind.**
- Vena comitae.
- Brachial Artery.
- Median nerve (above).
- Coraco-brachialis.
- Biceps.

**Inner side.**
- Vena comitae.
- Internal cutaneous and Ulnar nerves.
- Median nerve (below).
- Basilic vein (upper half).

**Relations.**—This artery is superficial throughout its entire extent, being covered, in front, by the integument, the superficial and deep fascia; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle. Behind, it is separated from the inner side of the humerus, above, by the long and inner heads of the Triceps, the musculo-spiral nerve and superior profunda artery intervening, and from the front of the bone, below, by the insertion of the Coraco-brachialis muscle and by the Brachialis anticus. By its outer side it is in relation with the commencement of the median nerve and the Coraco-brachialis and Biceps muscles, which slightly overlap the artery. By its inner side its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. It is accompanied by two vena comites, which lie in close contact with the artery, being connected together at intervals by short transverse communicating branches.

SURGICAL ANATOMY OF THE BEND OF THE ELBOW.

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the base of which is directed upward toward the humerus.
and the sides of which are bounded, externally, by the Supinator longus; internally, by the Pronator radii teres; its floor is formed by the Brachialis anticus and Supinator brevis. This space, cubital fossa, contains the brachial artery with its accompanying veins, the radial and ulnar arteries, the median and musculo-spiral nerves, and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, in front, by the integument, the superficial fascia, and the median basilie vein, the vein being separated from direct contact with the artery by the bicipital fascia. Behind, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid head of the Pronator radii teres. The tendon of the Biceps lies to the outer side of the space, and the musculo-spiral nerve still more externally, lying upon the Supinator brevis and partly concealed by the Supinator longus.

Peculiarities of the Brachial Artery as regards its Course.—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps, and descend toward the inner condyle of the humerus, where it usually curves round a prominence of bone, to which it is connected by a fibrous band; it then inclines outward, beneath or through the substance of the Pronator radii teres muscle, to the bend of the elbow. The variation bears considerable analogy with the normal condition of the artery in some of the carnivora; it has been referred to above in the description of the humerus (page 250).

As regards its Division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The point of bifurcation may be above or below the usual point, the former condition being by far the more frequent. Out of 481 examinations recorded by Mr. Quain, some made on the right and some on the left side of the body, in 386 the artery bifurcated in its normal position. In one case only was the place of division lower than usual, being two or three inches below the elbow-joint. In 94 cases out of 481, or about 1 in 5½, there were two arteries instead of one in some part or in the whole of the arm.

There appears, however, to be no correspondence between the arteries of the two arms with respect to their irregular division; for in 61 bodies it occurred on one side only in 43; on both sides, in different positions, in 13; on both sides, in the same position, in 5.

The point of bifurcation takes place at different parts of the arm, being most frequent in the upper part, less so in the lower part, and least so in the middle, the most usual point for the application of a ligature: under any of these circumstances two large arteries would be found in the arm instead of one. The most frequent (in three out of four) of these peculiarities is the high division of the radial. That artery often arises from the inner side of the brachial, and runs parallel with the main trunk to the elbow, where it crosses it, lying beneath the fascia; or it may perforate the fascia and pass over the artery immediately beneath the integument.

The ulnar sometimes arises from the brachial high up, and then occasionally leaves that vessel at the lower part of the arm, and descends toward the inner condyle. In the forearm it gen-
erally lies beneath the deep fascia, superficial to the flexor muscles; occasionally between the integument and deep fascia, and very rarely beneath the flexor muscles.

The interosseous artery sometimes arises from the upper part of the brachial or axillary; as it passes down the arm it lies behind the main trunk, and at the bend of the elbow regains its usual position.

In some cases of high division of the radial the remaining trunk (ulnar interosseous) occasionally passes, together with the median nerve, along the inner margin of the arm to the inner condyle, and then passing from within outward, beneath or through the Pronator radii teres, regains its usual position at the bend of the elbow.

Occasionally the two arteries representing the brachial are connected at the bend of the elbow by a short transverse branch, and are even sometimes reunited.

Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or axillary arteries with one of the arteries of the forearm or a branch from them. These vessels usually join the radial.

**Varieties in Muscular Relations.**—The brachial artery is occasionally concealed in some part of its course by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anteius and Pronator radii teres muscles.

**Surface Marking.**—The direction of the brachial artery is marked: when the arm is extended and supinated, by a line drawn from the junction of the anterior and middle third of the space between the anterior and posterior folds of the axilla; that is to say from the inner side of the prominence of the Coraco-brachialis muscle to the point midway between the condyles of the humerus which corresponds to the depression along the inner border of the Coraco-brachialis and Biceps.

In the upper part of its course the artery lies internal to the humerus, but below it is in front of that bone.

**Surgical Anatomy.**—Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outward; and if in the lower part, from before backward, as the artery lies on the inner side of the humerus above and in front below. The most favorable situation is about the middle of the arm, where it lies on the tendon of the Coraco-brachialis on the inner flat side of the humerus.

The application of a ligation to the brachial artery may be required in case of wound of the vessel and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margin of the Coraco-brachialis and Biceps, the known course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery, and two minute connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscular fibre is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

In the upper third of the arm the artery may be exposed in the following manner: The patient being placed horizontally upon a table, the affected limb should be raised from the side and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axilla. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venae comitantes are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed round the artery from the inner to the outer side.

If two arteries are present in the arm in consequence of a high division, they are usually placed side by side: and if they are exposed in an operation, the surgeon should endeavor to ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligation may be applied accordingly; or if pulsation or hemorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line toward the inner condyle of the humerus, or in the usual position of the brachial, but deeply placed beneath the common trunk: a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be

---

1 See Struther's *Anatomical and Physiological Observations.*
exposed lying upon the artery (sometimes beneath); this being drawn inward and the muscle outward, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally toward the Biceps, rather than inward or backward toward the Triceps.

The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery.

**Collateral Circulation.**—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the base is tied below the origin of the profunda arteries, the circulation is maintained by the branches of the profunda, anastomosing with the recurrent radial, ulnar, and interosseous arteries. In two cases described by Mr. South,\(^1\) in which the brachial artery had been tied some time previously, in one "a long portion of the artery had been obliterated, and sets of vessels are descending on either side from above the obliteration, to be received into others which ascend in a similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quill passes from the upper to the lower open part of the artery."

The branches of the brachial artery are—the

<td></td>
</tr>
</tbody>
</table>

The **superior profunda** arises from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backward to the interval between the outer and inner heads of the Triceps muscle, accompanied by the musculo-spiral nerve; it winds round the back part of the shaft of the humerus in the spiral groove, between the Triceps and the bone, to the outer side of the humerus just above the external condyle, where it divides into two terminal branches. One of these pierces the external intermuscular septum, and descends to the space between the Brachialis anticus and Supinator longus, where it anastomoses with the recurrent branch of the radial artery; while the other, the **posterior articular**, descends along the back of the external intermuscular septum to the back part of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (Fig. 366). The superior profunda supplies the Triceps muscle and gives off a nutrient artery to the upper end of the humerus. Near its commencement it sends off a branch which passes upward between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex artery, and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer condyle of the humerus.

The **nutrient artery** of the shaft of the humerus arises from the brachial, about the middle of the arm. Passing downward it enters the nutrient canal of that bone near the insertion of the Coraco-brachialis muscle.

The **inferior profunda**, of small size, arises from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the Triceps muscle to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It also supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The **anastomotica magna** arises from the brachial about two inches above the

---

\(^1\) Chelins's *Surgery*, vol. ii. p. 254. See also White's engraving, referred to by Mr. South, of the anastomosing branches after ligature of the brachial, in White's *Cases in Surgery*. Porta also gives a case (with drawings) of the circulation after ligature of both brachial and radial (*Alterazioni Patologiche delle Arterie*).
elbow-joint. It passes transversely inward upon the Brachialis anticus, and, piercing the internal intermuscular septum, winds round the back part of the humerus between the Triceps and the bone, forming an arch above the olecranon fossa by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the Brachialis anticus, branches ascend to join the inferior profunda, and others descend in front of the inner condyle to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the Triceps.

The muscular are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coraco-brachialis, Biceps, and Brachialis anticus muscles.

The Anastomosis around the Elbow-joint (Fig. 366).—The vessels engaged in this anastomosis may be conveniently divided into those situated in front and behind the internal and external condyles. The branches anastomosing in front of the internal condyle are the anastomotica magna, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those behind the internal condyle are the anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing in front of the external condyle are the radial recurrent and one of the terminal branches of the superior profunda. Those behind the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are the anastomotica magna, the interosseous recurrent, and one of the terminal branches of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent, joining with the anastomotica magna and posterior ulnar recurrent (Fig. 366).

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that in front of the external condyle.

Radial Artery.

The Radial Artery appears, from its direction, to be the continuation of the brachial, but in size it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist; it then winds backward, round the outer side of the carpus, beneath the extensor tendons of the thumb, and, finally, passes forward, between the heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the deep palmar arch. At its termination it inosculates with the deep branch of the ulnar artery. The relations of this vessel may thus be conveniently divided into three parts—viz. in the forearm, at the back of the wrist, and in the hand.

Relations.—In the forearm this vessel extends from opposite the neck of the radius to the fore part of the styloid process, being placed to the inner side of the shaft of the bone above and in front of it below. It is superficial throughout its entire extent, being covered by the integument, the superficial and deep fasciae, and slightly overlapped above by the Supinator longus. In its course downward it lies upon the tendon of the Biceps, the Supinator brevis, the radial origin of the Flexor sublimis digitorum, the Pronator radii teres, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Supinator longus and the Pronator radii teres; in its lower two-thirds, between the tendons of the Supinator longus and the Flexor carpi radialis. The radial nerve lies along the outer side of the artery in the middle third of its course, and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by venae comites throughout its whole course.

- Pronator quadratus.
- Radius.

At the wrist, as it winds round the outer side of the carpus from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins and a filament of the musculocutaneous nerve.

In the hand it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it inosculates with the communicating branch from the ulnar artery, forming the deep palmar arch. It lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, the Lumbricales, the Opponens, and Flexor brevis minimi digitii. Alongside of it is the deep branch of the ulnar nerve, but running in the opposite direction; that is to say, from within outward.

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial than from the lower part of this vessel. The variations in the position of this vessel in the arm and at the bend of the elbow have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found lying over the fascia instead of beneath it. It has also been observed on the surface of the Supinator longus, instead of along its inner border; and in turning round the wrist it has been seen lying over, instead of beneath, the extensor tendons.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the fore part of the styloid process of the radius.

Surgical Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and such-like accidents. The injury is often followed by a traumatic aneurism, for which the old operation of laying open the sac and securing the vessel above and below is required.

The operation of tying the radial artery is required in cases of wounds either of its trunk or of some of its branches, or for aneurism; and it will be observed that the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed, but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel and from its being overlapped by the Supinator longus muscle.

To tie the artery in the upper third an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided and the Supinator longus drawn a little outward, the artery will be exposed. The venae comitantes should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Supinator longus. In this situation the radial nerve
lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Supinator longus and Flexor carpi radialis muscles.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

In the Forearm:
- Radial Recurrent
- Muscular
- Anterior Carpal
- Superficialis Volar
- Posterior Carpal
- Metacarpal

Wrist:
- Dorsales Pollicis
- Dorsalis Indicis
- Princeps Pollicis
- Radialis Indicis
- Perforating
- Interosseous

Hand:
- Palmar Recurrent

The radial recurrent is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve lying on the Supinator brevis, and then between the Supinator longus and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with one of the terminal branches of the superior profunda.

The muscular branches are distributed to the muscles on the radial side of the forearm.

The anterior carpal is a small vessel which arises from the radial artery near the lower border of the Pronator quadratus, and, running inward in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. From the arch thus formed branches descend to supply the articulations of the wrist.

The superficialis volar arises from the radial artery, just where this vessel is about to wind round the wrist. Running forward, it passes between the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size:
usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The posterior carpal arises from the radial artery beneath the extensor tendons of the thumb; crossing the carpus transversely to its inner border, it anastomoses with the posterior carpal branch of the ulnar, forming the posterior carpal arch, which is joined by the termination of the posterior interosseous artery. From this arch are given off descending branches, the dorsal interosseous arteries for the third and fourth interosseous spaces, which run forward on the muscles and divide into dorsal digital branches which supply the adjacent sides of the middle, ring, and little fingers respectively, communicating with the digital arteries of the superficial palmar arch. At their origin they anastomose with the superior perforating branches from the deep palmar arch, and at the clefts of the fingers send off inferior perforating branches to the corresponding palmar digital arteries.

The metacarpal (first dorsal interosseous branch) arises beneath the extensor tendons of the thumb, sometimes with the posterior carpal artery; running forward on the Second dorsal interosseous muscle, it communicates, behind, with the corresponding superior perforating branch of the deep palmar arch; and in front it divides into two dorsal digital branches, which supply the adjoining sides of the index and middle fingers, inosculating with the digital branch of the superficial palmar arch. It also has a similar but more constant inferior perforating branch.

The dorsalis indicis are two vessels which run along the sides of the dorsal aspect of the thumb. They arise separately, or by a common trunk, near the base of the first metacarpal bone.

The dorsalis indicis runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.

The princeps pollicis arises from the radial just as it turns inward to the deep part of the hand; it descends anterior to the Abductor indicis and between the Adductor pollicis muscles, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx, where it divides into two branches, which run along the sides of the palmar aspect of the thumb and form an arch on the under surface.
of the last phalanx, from which branches are distributed to the integument and pulp of the thumb.

The radialis indicis arises close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The superior perforating arteries, three in number, pass backward between the heads of the last three Dorsal interossei muscles, to inosculate with the dorsal interosseous arteries.

The palmar interosseous, three or four in number, are branches of the deep palmar arch; they run forward upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The palmar recurrent branches arise from the concavity of the deep palmar arch. They pass upward in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

Ulnar Artery.

The Ulnar Artery, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and crosses obliquely the inner side of the forearm, to the commencement of its lower half; it then runs along its ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches, superficial and deep palmar.

Relations in the Forearm.—In its upper half it is deeply seated, being covered by all the superficial flexor muscles, excepting the Flexor carpi ulnaris; it is crossed by the median nerve (deep head of Pronator radii teres intervening), which lies just above to its inner side, and it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the lower half of the forearm it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciae, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two vena comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

Flexor profundus digitorum.

At the wrist (Fig. 364) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone. The ulnar nerve lies at the inner side, and somewhat behind the artery.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source of origin than the axillary.
Variations in the position of this vessel are more frequent than in the radial. When its origin is normal the course of the vessel is rarely changed. When it arises high up it is almost invariably superficial to the flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

**Surface Marking.**—On account of the curved direction of the ulnar artery the line on the surface of the body which indicates its course is somewhat complicated. First, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. Secondly, draw a line from the centre of the hollow in front of the elbow-joint to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

**Surgical Anatomy.**—The application of a ligature to this vessel is required in cases of wound of the artery or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the superficial flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed, and must be drawn aside. Some little distance below the nerve the artery will be found accompanied by its venae comites, and may be ligatured by passing the needle from within outward. In the middle and lower third of the forearm this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its venae comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

The branches of the ulnar artery may be arranged in the following groups:

- **Anterior Ulnar Recurrent.**
- **Posterior Ulnar Recurrent.**
- **Intercostal**
  - **Anterior Intercostal.**
  - **Posterior Intercostal.**
- **Muscular.**
- **Anterior Carpal.**
- **Posterior Carpal.**
- **Superficial Palmar Arch.**
- **Deep Palmar or Communicating.**

The **anterior ulnar recurrent** (Fig. 365) arises immediately below the elbow-joint, passes upward and inward between the Brachialis anticus and Pronator radii teres, supplies those muscles, and, in front of the inner condyle, anastomoses with the anastomotica magna and inferior profunda.

The **posterior ulnar recurrent** is much larger, and arises somewhat lower than the preceding. It passes backward and inward, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon it lies beneath the Flexor carpi ulnaris, ascending between the heads of that muscle, beneath the ulnar nerve; it supplies the neighboring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries (Fig. 366).

The **interosseous artery** (Fig. 365) is a short trunk about an inch in length, and of considerable size, which arises immediately below the tuberosity of the radius, and, passing backward to the upper border of the interosseous membrane, divides into two branches, the **anterior** and **posterior interosseous**.

The **anterior interosseous** passes down the forearm on the anterior surface of the interosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis muscles, giving off in this situation muscular branches and the nutrient arteries of the radius and ulna. At the upper border of the Pronator quadratus a branch descends beneath the muscle to anastomose in front of the carpus with
branches from the anterior carpal and deep palmar arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, gets to the back of the forearm, and anastomoses with the posterior interosseous artery (Fig. 366). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives off a long, slender branch, the median artery, which accompanies the median nerve and gives offsets to its substance. This artery is sometimes much enlarged. It also gives off nutrient branches to the radius and ulna about the middle of the forearm.

The posterior interosseous artery passes backward through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery.

Then, continuing its course over the head of the ulna, it joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the interosseous recurrent branch.

The interosseous recurrent artery is a large vessel which ascends to the interval between the external condyle and olecranon, on or through the fibres of the Supinator brevis, but beneath the Anconeus, anastomosing with a branch from the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The muscular branches are distributed to the muscles along the ulnar side of the forearm.

The anterior carpal is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus, and inosculates with a corresponding branch of the radial artery.
The posterior carpal arises immediately above the pisiform bone, and winds backward beneath the tendon of the Flexor carpi ulnaris; it passes across the dorsal surface of the carpus beneath the extensor tendons, anastomosing with a corresponding branch of the radial artery, and forming the posterior carpal arch. Immediately after its origin it gives off a small branch which runs along the ulnar side of the metacarpal bone of the little finger, forming one of the metacarpal arteries, and supplies the ulnar side of the dorsal surface of the little finger. (See also page 600.)

The deep palmar or communicating branch (Fig. 365) passes deeply inward between the Abductor minimi digiti and Flexor brevis minimi digiti near their origins; it anastomoses with the termination of the radial artery, completing the deep palmar arch.

The Superficial Palmar Arch.—The superficial palmar arch passes outward across the palm of the hand, describing a curve, with its convexity forward to the space between the ball of the thumb and the index finger, where the arch is completed by its anastomosing with a branch from the radialis indicis, though sometimes the arch is completed by its anastomosing with the superficialis volæ branch of the radial artery.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis, and the palmar fascia. It lies upon the annular ligament, origin of the muscles of the little finger, the tendons of the superficial flexor of the fingers, and, the divisions of the median and ulnar nerves.

Branches of the Superficial Palmar Arch.

Digital.

The digital branches (Fig. 364), four in number, are given off from the convexity of the superficial palmar arch. They supply the ulnar side of the little finger and the adjoining sides of the little, ring, middle, and index fingers, the radial side of the index finger and thumb being supplied from the radial artery. The digital arteries at first lie superficial to the flexor tendons, but as they pass forward with the digital nerves to the clefts between the fingers they lie between them, and are there joined by the interosseous branches from the deep palmar arch. The digital arteries on the sides of the fingers lie behind the digital nerves; and about the middle of the last phalanx the two branches for each finger form an arch, from the convexity of which branches pass to supply the pulp of the finger.

Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone and carried downward as far as the middle third of the palm, and then curved outward on a level with the upper end of the cleft between the thumb and index finger.

The deep palmar arch is situated about half an inch nearer to the carpus.
THE THORACIC AORTA.

605

Surgical Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the wound in the superficial tissues is extensive, it may be possible to secure the bleeding ends of the vessel; but when there is a small punctured wound, as from a penknife or piece of glass, pressure systematically applied is probably the best course of treatment, as there is difficulty in reaching the wounded vessel without damaging important structures. At the same time it must be admitted that pressure applied to the palm of the hand to arrest haemorrhage from a wound of one of the palmar arches, especially the deep arch, is apt to be followed by sloughing, owing to the rigidity of the parts and the facility with which a considerable amount of pressure can be applied. In wounds of the deep palmar arch a ligature may be applied to the bleeding points from the dorsum of the hand by resection of the upper part of the third metacarpal bone. It is useless in these cases to ligature one of the arteries of the forearm alone, and indeed simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest haemorrhage it is expedient to apply a ligature to the brachial artery.

THE DESCENDING AORTA.

ARTERIES OF THE TRUNK.

The Descending Aorta is divided into two portions, the thoracic and abdominal, in correspondence with the two great cavities of the trunk in which it is situated.

THE THORACIC AORTA.

The Thoracic Aorta commences at the lower border of the fourth dorsal vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the last dorsal vertebra. At its commencement it is situated on the left side of the spine; it approaches the median line as it descends, and at its termination lies directly in front of the column. The direction of this vessel being influenced by the spine, upon which it rests, it describes a curve which is concave forward in the dorsal region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable. It is contained in the back part of the posterior mediastinum.

Relations.—It is in relation, in front, from above downward, with the left pulmonary artery, the left bronchus, the pericardium, and the oesophagus; behind, with the vertebral column and the vena azygos minor; on the right side, with the vena azygos major and thoracic duct; on the left side, with the left pleura and lung. The oesophagus with its accompanying nerves lies at first on the right side of the aorta, but at the lower part of the thorax it gets in front of the aorta, and close to the Diaphragm is situated to its left side.

The aorta is occasionally found to be obliterated at a particular spot—viz. at the junction of the arch with the thoracic aorta, just below the ductus arteriosus. Whether this is the result of disease or of congenital malformation is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the Pathological Transactions, vols. viii. and x. In the former (p. 160) Mr. Sydney Jones thus sums up the detailed description of the
